A Dissertation Submitted to the Faculty of Science.
University of the Witwatersrand, Johannesburg
for the degree of Master of Science

Johannesburg 1984
DECLARATION

I declare that this dissertation is my own, unaided work.

It is being submitted for the degree of Master of Science in the University of the Witwatersrand, Johannesburg. It has not been submitted before for any degree or examination in any other University.

GARY JAMES KELLY

[Date]
ABSTRACT

This dissertation reviews the theory and methods of three areas in time-series analysis - periodogram analysis, spectral analysis and Box-Jenkins modelling. Once the basic mathematical necessities and definitions have been set down, the relationship between the periodogram and spectrum is illustrated.

The statistical properties of both the periodogram and spectrum are provided, as well as the practical problems involved when analysing data using these techniques. As a result of the complexities of the spectrum, more emphasis is placed on periodogram analysis.

The time-domain approach to time-series analysis consists of an introduction to, and explanation of the Box-Jenkins modelling theory. Techniques (for example, the autocorrelation function and inverse autocorrelation function) and the theory behind them for identifying, estimating and checking models, are given.

Forecasting and Box-Jenkins seasonal models are only touched upon, as are nonlinear time-series models. An application of all the major techniques is provided.
For my family

## BIBLIOGRAPHY

B1 - B9
A discrete univariate time-series is a sequence of observations ordered and equally spaced in time. This dissertation reviews the theory and methods of three areas in time-series analysis and presents an application thereof. The object of this study is to present a unified treatment of the techniques involved and to gain a working knowledge of these procedures. The application of these techniques has necessitated the development of a suite of computer programs for performing time-series analysis.

There are two major approaches to the study of time-series processes - time-domain and frequency-domain analysis. In the context of this work, I shall consider the former as consisting of an approach generally called Box-Jenkins modelling and the latter of the two techniques - periodogram analysis and spectrum analysis.

Once the basic mathematical necessities and definitions have been set down, the periodogram is introduced as a tool useful for identifying (and removing) any periodic tendencies in the data. Verification of its statistical properties and notes relating to these are given. Thereafter, the link between the periodogram and (theoretical) spectrum is forged.

In considering the spectrum and spectral analysis, the mathematical theory behind these concepts is discussed and an introduction to, and the properties of, windowed spectral estimates are given. The approach used here is from a periodogram viewpoint. The problems in setting up a spectral analysis are also considered. This completes the analysis in the frequency-domain.
The time-domain approach consists of an introduction to the Box-Jenkins modelling theory and its statistical properties. Tools (and the theory behind them) for identifying, estimating and 'checking' models are given. 'Checking' will involve ascertaining whether the residuals from the fitted model are approximately white noise variables.

Box-Jenkins seasonal models will only be mentioned in passing as the general approach adopted here is to remove any seasonal components by using the periodogram (i.e. harmonic analysis) and to apply the Box-Jenkins theory to the residuals. The reason for this is that if the time-series is seasonal the usual Box-Jenkins approach of differencing implies that several terms may be lost in order to induce the necessary state of stationarity for Box-Jenkins stationary models. This is not necessary when using periodogram analysis. However, the price you may have to pay for this is a lack of parsimony (i.e. too may not be a minimum number of parameters in the model).

Spectral analysis is considered as subsidiary to periodogram analysis due to the problems (both practical and theoretical) involved in calculating the spectrum. However one may 're-generate' the data based on the fitted model and hence compute a spectral estimate and compare this with the approximate spectrum of the original data.

As in the case of Box-Jenkins seasonal models, forecasting (future) values will only be touched upon, as the emphasis of this study is rather on modelling. However, it follows that if a reasonable model has been formulated, forecasts should not prove too difficult to obtain. (The only difficulty arising may be i
particular approaches and methods are given in the text. This application has necessitated the creation of a battery of computer programs for time-series analysis. These programs have been written in a conversational mode and are as automatic/objective as possible at the moment. An idea for the future is to make this package fully automatic thus enabling the layman to perform a time-series analysis. A description of the programs is given in an appendix.

It is worthwhile stressing that only discrete univariate time-series are considered in this work. Any continuous time-series may be converted into a discrete one by sampling at equal time intervals. Thus the theory presented here, i.e. in a way, indirectly applicable to continuous time-series. No multivariate time-series theory is considered as univariate series are more common, and more work has been done in this field.

The main sources for reference material were Box and Jenkins (1976), Priestley (1981) (both volumes 1 and 2), Bloomfield (1976) and to a lesser degree, Chatfield (1980). Jottman (1981) proved to be an invaluable asset as far as a non-theoretical (practical) approach was concerned and also served as a readable introductory text.

CHAPTER I: INTRODUCTION AND NECESSARY THEORY

1.1 INTRODUCTION

When we look at any object, one of the first things we notice is its colour. We generally see a mixture of basic colours, but cannot say how much red or blue light the object contains. Instead we observe the overall effect.

To distinguish the various colours, the light from the object must be passed through a prism and we may then determine the ‘strength’ of different colours. This information is called the spectrum of light.

In a similar fashion any wave-like phenomenon can also be analysed by breaking the wave into a composition of sine and cosine waves of forms, with varying amplitudes and frequencies. Now wave-like phenomena are generally associated with ocean or radio waves, and we usually see some pattern in those waves – i.e. they repeat themselves after certain time intervals. This type of phenomenon is called a periodic function.

Definition 1:
A function \( f(x) \) (where \( x \) is a measure of ‘time’) is periodic if \( f(x) = f(x+h) \) (where \( h \) is some number and \( h \) is said to be the period of \( f(x) \)).

\( \cos(\omega t) \) is one of the most familiar periodic functions. If it has period \( h \), then \( \omega h = \pi \) and \( \omega \) is called the angular frequency (expressed in radians per unit time). \( \omega \) is called the amplitude.
This function, together with $b\sin(wx)$, can be considered as building blocks for all other periodic functions, since any 'well-behaved' periodic function of finite period $h$, can be expressed as a (possibly infinite) sum of weighted sine and cosine waves. This remarkable result will be discussed more fully in section 1.5 but can be written more formally as

**Theorem 1: Fourier's theorem**

If $f(x)$ is a well-behaved periodic function of period $h$, then $f(x)$ may be written as a Fourier series in the form

$$f(x) = \sum_{k=0}^{\infty} a_k \cos\left(\frac{2\pi k x}{h}\right) + b_k \sin\left(\frac{2\pi k x}{h}\right)$$  \hspace{1cm} (1.1)

where $a_0, a_1, \ldots$ and $b_0, b_1, \ldots$ are constants to be determined.

(For proof see section 1.5)

In a similar fashion if $f(x)$ is nonperiodic, we may still regard it as periodic but with infinite period and hence

**Theorem 2**

If $f(x)$ is a nonperiodic function, then it can be rewritten as

$$f(x) = \int_{-\infty}^{\infty} a(w)\cos(wx) + b(w)\sin(wx) \, dw$$  \hspace{1cm} (1.2)

where $a(w)$ and $b(w)$ are functions whose form is still to be determined.

(For proof see section 1.6)

absolutely integrable over $(-\infty, \infty)$ with a finite number of discontinuities
For computational purposes we may define

\[ J_r = \begin{cases} \frac{1}{2}(a - ib) & r > 0 \\ a_0 & r = 0 \\ \frac{1}{2}(a + ib) & r < 0 \end{cases} \]  

or analogously

\[ J(w) = \begin{cases} \frac{1}{2}(a(w) - ib(w)) & w > 0 \\ a(0) & w = 0 \\ \frac{1}{2}(a - ib(w)) & w < 0 \end{cases} \]  

and then we may rewrite (1.1) and (1.2), respectively, as

\[ f(x) = \sum_{k=-\infty}^{\infty} J_k e^{iw_k x} \]  

(where \( w_k = 2^{-k} \) and \( w_{-k} = -w_k \))

and

\[ f(x) = \int_{\mathbb{R}} J(w)e^{iwx}dw \]  

Definition 2

\( J(w) \) (or analogously \( J_k \)) is called the Fourier transform of \( f(x) \).

Thus if we are prepared to accept theorems 1 and 2, it turns out that any well-behaved function may be written as some function of its Fourier transform. So if we have a set of data which follows some functional form, we may estimate this functional form merely by estimating the Fourier transform of the data.

So given any set of data ordered in time, it is possible to 'model' the process which generated it simply by approximating the generating process by the Fourier transform of the data.
THE MEANING OF THE FOURIER TRANSFORM

Theorem 1: Let sin and cos, valid (and this validity will be shown later), assume that any periodic and nonperiodic functions be written in sine and cosine functions, then it may be shown, see section (6), that the 'energy' given off by the process may be intial, is equal to the sum of the amounts of energy given off by each of the sine and cosine terms.

The energy given by any sine or cosine term is proportional to the square of its amplitude and so for periodic processes, the contributions of the sine terms in the case where \( f(x) \) is periodic,

\[ \int |\sin(x)|^2 \, dx \quad \text{(by theorem 1)} \]

\[ \text{is proportional to a}_{\text{s}}^2 \quad \text{and} \quad b_{\text{c}}^2 \]

2 against for \( w_k \); give the relative intensity of various sine and cosine terms to the total energy.

The total contribution formed an energy spectrum.

The contributions can only be considered if a periodic process has a representation, and periodic processes must be considered for periodic processes must be represented by these representations, and we say these periodic processes have a periodic spectrum

\[ \text{so } (\tilde{f}(\omega))^2 \quad \text{and} \quad (\tilde{f}(-\omega))^2 = (\tilde{f}(\omega))^2 \]

In this sense, the energy density is only need be plotted for positive \( \omega \).

For a more detailed description of the Fourier transform see, for instance, H. D. E. STUART [1961].
1.3 STOCHASTIC AND STATIONARY PROCESSES

So far no mention has been made of the time-series, so we are entitled to ask "How does the theory of section 1.1 and 1.2 help us?"

We shall see from the following definitions (some of which we shall only see the relevance of at a later stage) exactly what bearing this theory has.

**Definition 3**

A random (or stochastic) process is such that for each t, the value $X(t)$ is a random variable. $X(t)$ is called a random process if the situation is such that for each t, we cannot determine theoretically a precise value of $X(t)$. Instead we have a range of values with an associated pdf (probability density function).

**Definition 4**

An observed record of a random process is merely one realization out of a whole collection of possible realizations.

**Definition 5**

For each t, $X(t)$ is a r.v. (random variable) and so accordingly $X(t)$ will have the same pdf as $X(s)$ (for all s) $P_t(x)$, say (if $X(t)$ is continuous) or $P_t(x_0)$, say (if $X(t)$ is a discrete r.v.)

At this point, I have changed notation from $f(x)$ to $X(t)$ since a time-series is dependent on time, i.e., $X(t)$ is a random variable i.e. $f(t) = X(t)$ ∀t.
Definition 6
A discrete time-series is a realization of a random process $X(t)$ only considered at the discrete time points $..., -1, 0, 1, 2, ...$ and denoted by $X_t$.

The theory of sections 1.1 and 1.2 concerning a function $f(x)$ is really for a deterministic function $f(x)$ (i.e. a function which for a particular value of $x$, we can determine $f(x)$). Does this then mean we may not apply this theory to a discrete time series which is a realization of a random process?

No. We are saved by the implications of Wiener's theory of generalized harmonic analysis (which is formulated in section 2.2) which states: each realization of a 'stationary' process can be expressed as a Fourier-Stieltjes (Wiener (1930)) transform of the form

$$X(t) = \int_{-\infty}^{\infty} s(t) \, dZ(w)$$

where $Z(w)$ is not necessarily differentiable but has the same form as $J(w)$ given by (1.4).

Saved? No - we have not yet defined what we mean by 'stationary'. If this stationarity condition does not impose too many restraints on our single realization (i.e. our time-series) we may then apply the theory of sections 1.1 and 1.2 and hence estimate some form of model.

Definition 7
A stationary process has the characteristic that its statistical properties do not change with time i.e. if $X_1$ is stationary, then $X(1), X(2), ...$ must each have the same pdf.
Definition 8

$X(t)$ is called strictly stationary if the joint distribution of $X(t_1), \ldots, X(t_n)$ is identical to that of $X(t_1+k), \ldots, X(t_n+k)$ for any set $t_1, \ldots, t_n$ and any $k$.

Definition 9

$X(t)$ is said to be stationary up to order $m$ if for any set $t_1, \ldots, t_n$ and any $k$, all the joint moments up to $m$ of $X(t_1), \ldots, X(t_n)$ exist and equal the corresponding moments of $X(t_1+k), \ldots, X(t_n+k)$.

Definition 10

A process is called Gaussian if all joint distributions of $X(t_1), \ldots, X(t_n)$ for any $n$ and sets $t_1, \ldots, t_n$ are multivariate normal.

Thus, we may in principle ascertain whether our time-series is stationary if it is not we seek some technique to induce stationarity and hence calculate Fourier transforms of the data.
1.4 THE AUTOCOVARIANCE AND AUTOCORRELATION FUNCTIONS

A special case of the stationarity concept is for stationarity of order \( m = 2 \). By definition this implies that

1. \( X(t) \) has the same mean, \( \mu \), \( \forall t \),
2. \( X(t) \) has the same variance, \( \sigma^2 \), \( \forall t \), and
3. the covariance between the values at any two time points, \( s \) and \( t \) say, depends only on \( (s-t) \)

So if \( X(t) \) is stationary up to order two, two functions, namely the autocovariance function (acovf) and the autocorrelation function (acrf) may be derived.

**Definition 1**

\[ \gamma(s) = \text{cov}(X(t), X(t-s)) \]
\[ = E[(X(t)-\mu)(X(t-s)-\mu)] = \gamma(0) \forall t, s \]

is defined to be the acvf and is independent of time by the definition of 2nd order stationarity.

**Similarly**

**Definition 2**

\[ \rho(s) = \gamma(s)/\gamma(0) \] \( \forall s \) is defined to be the acrf.

When \( X(t) \) is a discrete time process i.e. \( \delta(t) = X(t), \quad \text{for } t = 0, \pm 1, \pm 2, \ldots \), the acvf has the following properties

1. \( \gamma(0) = \sigma^2 \) the variance of \( X_n \),
2. \( \gamma(s) \leq \gamma(0) \) (\( \forall s \) since \( \gamma(s) \leq \sigma^2 \) for all \( s \))
3. if \( X_n \) is realvalued then \( \gamma(-s) = \gamma(s) \) \( \forall s \geq 0 \) and
4. \( \gamma(s) \) is positive semidefinite.

(related properties may be derived when \( X(t) \) is a continuous-time process)
The value and uses of these functions is not immediately clear, but they will be utilized at a later stage.

1.5 AN OUTLINE PROOF OF FOURIER’S THEOREM (THEOREM 1)

Theorem 1, Fourier’s theorem, states that if \( f(x) \) is a well-behaved periodic function of period \( h \), then \( f(x) \) may be written as a Fourier series in the form

\[
f(x) = \sum_{k=0}^{\infty} \left[ a_k \cos\left( \frac{2\pi k x}{h} \right) - b_k \sin\left( \frac{2\pi k x}{h} \right) \right]
\]  

(where \( a_k, b_k \) are some constants).

Without loss of generality, suppose \( h = 2 \pi \). Now the following functions, namely \( \cos(t), \sin(t), \cos(2t), \sin(2t), \ldots \), are all periodic with period \( 2\pi \), and any linear combination of them will also be periodic with period \( 2\pi \). Then we must show that if \( X(t) \) is a function of \( t \) with period of \( 2\pi \), then we can represent \( X(t) \) by

\[
X(t) = \frac{1}{2} a_0 + \sum_{k=1}^{\infty} a_k \cos(kt) + b_k \sin(kt)
\]  

This will prove Fourier’s theorem.

The reason for using \( \frac{1}{2} a_0 \) instead of \( a_0 \) is simply for notational purposes.

Note that \( a_k \) and \( b_k \) are called Fourier coefficients and the term corresponding to \( k = 1 \) is called the fundamental, that again, I use \( X(t) \) instead of \( f(x) \) for notational continuity.
corresponding to \( k = 2 \) the first harmonic, that corresponding to
\( k = 3 \), the second harmonic, etc.

If we multiply both sides of (1.8) by \( \cos(jt) \) \((j \text{ some integer} \geq 0)\) and integrate over \( t \) from \(-\infty\) to \( \infty\), then if the RHS of (1.8)
can be integrated term by term (which is possible if the series is
uniformly convergent over the interval \((-\infty, \infty)\)) then we have

\[
\int_{-\infty}^{\infty} X(t) \cos(jt) dt = \frac{1}{2} a_0 + \sum_{k=1}^{\infty} \left[ a_k \int_{-\infty}^{\infty} \cos(kt) \cos(jt) dt - b_k \int_{-\infty}^{\infty} \sin(kt) \cos(jt) dt \right] \quad (1.9)
\]

\( j = 0, 1, 2, \ldots \)

(if we assume the Fourier representation (1.8) is permissible)

Now since

\[
\int_{-\infty}^{\infty} \cos(kt) \cos(jt) dt = 0 \quad j \neq k
\]

\[
\int_{-\infty}^{\infty} \sin(kt) \cos(jt) dt = 0 \quad \forall j, k
\]

\[
\int_{-\infty}^{\infty} \sin(kt) \sin(jt) dt = 0 \quad j \neq k
\]

then we may rewrite (1.9) as

\[
\int_{-\infty}^{\infty} X(t) \cos(jt) dt = a_j \int_{-\infty}^{\infty} \cos(jt) dt
\]

\[
a_j = \frac{1}{\pi} \int_{-\infty}^{\infty} X(t) \cos(jt) dt \quad j = 0, 1, 2, \ldots \quad (1.10)
\]

i.e.
\[
a_j \int_{-\infty}^{\infty} \cos(jt) dt
\]
[the use of a_ instead of a now becomes apparent - since we now note that (1.10) includes the case j = 0].

In a similar manner, it may be shown that

\[ b_j = \frac{1}{\pi} \int_{-\pi}^{\pi} X(t) \sin(jt) dt \quad j = 1, 2, ... \]  

(1.11)

(1.10) and (1.11) are called the Euler-Fourier formulae.

By assuming the series \( X(t) \) is uniformly convergent on \((\pi, \pi)\), we eliminate the problem of integrating term by term. However, we are still not justified in writing \( X(t) \) in the form of a Fourier representation \((1.7)\). Or are we?

If we define \( a_0 \) and \( b_j \) by (1.10) and (1.11) respectively, then it may be shown that with these coefficients the RHS of (1.8) represents the function \( X(t) \). The only questions to be asked are (a) do (1.10) and (1.11) always yield finite values? and (b) if so, does (1.8) (i.e., the RHS of (1.8)) always converge to \( X(t) \)?

(a) is answered by insisting that \( X(t) \) be absolutely integrable over \((\pi, \pi)\). (b) is solved by restricting \( X(t) \) to a finite number of discontinuities and also a finite number of maxima and minima (these conditions are termed the Dirichlet conditions).

Under the above assumptions, we can claim that any (periodic) function has a Fourier series representation and hence any (deterministic) time-series also has one. If we estimate the \( a_k \) and \( b_k \), we may determine at what frequencies the time-series has (significant) power.
In summary then, if \( X(t) \) is a well-behaved periodic function, of period 2\( \pi \), we may represent \( X(t) \) by

\[
X(t) = \frac{1}{2} X_0 + \sum_{k=1}^{\infty} \left( a_k \cos(kt) + b_k \sin(kt) \right) \quad \forall t
\]

if

(i) \( X(t) \) is uniformly convergent on \((-\infty, \infty)\)

(ii) \( X(t) \) is absolutely integrable over \((-\infty, \infty)\)

(iii) \( X(t) \) has a finite number of discontinuities in \((-\infty, \infty)\)

(iv) \( X(t) \) has a finite number of maxima and minima in \((-\infty, \infty)\)

Notes

(a) Jordan's test (Theorem 3)

If \( X(t) \) is of bounded variation in the neighbourhood of \( t = t_0 \), then its Fourier series converges to the sum

\[
\frac{1}{\pi} \left( X(t_0^-) - X(t_0^+) \right)
\]

\( X(t) \) is of bounded variation in \((a, b)\) if for any sub-division of this interval, \( a = t_0 < t_1 < \cdots < t_n = b \),

\[
\sum_{i=0}^{n-1} \left( |X(t_{i+1}) - X(t_i)| \right)
\]

is bounded by a constant whose value is independent of the form of the subdivision.

For proof, see Titchmarsh (1939)
(b) Theorem 1

If \( X(t) \) has a finite number of discontinuities as well as a finite number of maxima and minima in \((-\infty, \infty)\) then its Fourier series converges (for all \( t \)) to

\[
\frac{1}{2} \left[ X(t-0) + X(t+0) \right]
\]

(for proof, use theorem 3)

hence

(c) Theorem 5

If \( X(t) \) is continuous and of bounded variation throughout \((-\infty, \infty)\), then its Fourier series converges for all \( t \) to \( X(t) \).

1.6 THE NONPERIODIC CASE (OUTLINE PROOF OF THEOREM 2)

The results of the last section only hold for the case where \( f(t) \) (or \( X(t) \)) is periodic (with finite period \( h \)). If \( X(t) \) is deterministic but not periodic, we would also like some Fourier representation if possible.

Simply define (or choose) some interval \((-\tau, \tau)\) and then define

\[
X(t) = \begin{cases} 
Y(t) & -\tau \leq t \leq \tau \\
Y(t+2p\tau) &= Y(t) & p = 1, 2, 3, \ldots
\end{cases}
\]

Then \( Y(t) \) is periodic with period \( 2\tau \), and so can be expressed in a Fourier series:

\[
Y(t) = \sum_{k=-\infty}^{\infty} \left( a_k \cos(2\pi k t) + b_k \sin(2\pi k t) \right)
\]

where \( a_k \) and \( b_k \) are determined by the coefficients of the \( X(t) \) in the interval \((-\tau, \tau)\).
Defining \( a_k \) as in (1.3) i.e.
\[
\begin{align*}
\frac{1}{2}(b_k - ib_k) & \quad k \neq 0 \\
\frac{1}{2}a_0 & \quad k = 0 \\
\frac{1}{2}(a_k + ib_k) & \quad k = 0
\end{align*}
\]
then
\[
Y(t) = \sum_{k=-\infty}^{\infty} \frac{1}{2} \frac{1}{2^{\frac{1}{2}k}} t^k \sum_{i=0}^{\infty} i^k \cdot i
\]
and so (see (1) and (11) below)
\[
Y(t) = \sum_{k=-\infty}^{\infty} \frac{1}{2} \frac{1}{2^{\frac{1}{2}k}} t^k \sum_{i=0}^{\infty} i^k \cdot i
\]
where
\[
\frac{1}{2} = w \quad k = \frac{1}{2}
\]
and so \((1.3)\) may be written as
\[
Z(t) = \sum_{k=0}^{\infty} \left( \frac{1}{2} \frac{1}{2^{\frac{1}{2}k}} t^k \sum_{i=0}^{\infty} i^k \cdot i \right)
\]
(by simply extending the proof in section 1.3 to deal with the case of period \( \frac{1}{2} \).

Note that this is not the same as (1.3) since (1.3) employs \( a_0 \) instead of \( \frac{1}{2}a_0 \). \( \frac{1}{2}a_0 \) is used for computational purposes.
(11) Using (1), it may be shown that

\[ J_k = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-2i\pi k \xi} \phi(\xi) d\xi \]

\[ = \frac{1}{2\pi} \int_{-\infty}^{\infty} \phi(x) e^{-i2\pi k x} dx \]

Now taking the limit as \( r \to \infty \) just gives

\[ X(t) = \int_{-\infty}^{\infty} J(\omega) e^{i\omega t} d\omega \]

(since \( x^* \to 0 \) and \( \lim_{r \to \infty} x^*_{-r} = y^*(r) \to \infty \) becomes a continuous set of points and hence summation becomes integration)

where

\[ J(\omega) = \int_{-\infty}^{\infty} x(t) e^{-i\omega t} dt \]

(11.12)

(These integrals make only if \( |x(t)| \) is absolutely integrable over \( [-\infty, \infty] \).

Let \( x^* = x' \) then

\[ X(t) = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{\infty} g(x') e^{-i\omega t} dx' \]

where

\[ g(x') = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{\infty} x(t) e^{i\omega t} dt \]

which then proves theorem 2.

(Note that \( g(x') = \frac{1}{(2\pi)^{1/2}} J(\xi') \))
THE SPECTRAL DENSITY FUNCTION

We assume a stationary stochastic process, or rather a single realization thereof, X(t). Henceforth, let w.l.o.g. assume E[X(t)] = 0.

Also, we assume X(t) is periodic and nor can we assume X(t) is absolutely integrable. Thus it would seem we cannot represent it as a Fourier series (since X(t) must either be periodic, or absolutely and absolutely integrable over (-\infty, \infty) - see section for the latter restriction).

To solve this problem, simply define another process, \( \hat{X}(t) \) as such that:

\[
\hat{X}(t) = \begin{cases} 
X(t) & \text{if } \exists \alpha \text{ such that } \alpha \in \mathbb{Q} \\
0 & \text{otherwise}
\end{cases}
\]  

(1.12)

Then we may write:

\[
X(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{X}(\alpha) e^{i\alpha t} \, d\alpha
\]

Moreover, given:

\[
\frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{X}(\alpha) e^{i\alpha t} \, d\alpha = \int_{-\infty}^{\infty} \hat{X}(\alpha) e^{i\alpha t} \, d\alpha
\]

(1.14)

Since \( \hat{X}(\alpha) \) or may not possess a Fourier integral, the limit of \( \int_{-\infty}^{\infty} \hat{X}(\alpha) e^{i\alpha t} \, d\alpha \) does not exist. But the total energy given by \( \int_{-\infty}^{\infty} \hat{X}(\alpha) \, d\alpha \) on the interval (-\infty, \infty) is equal to:

\[
\sum_{\alpha \in \mathbb{Q}} |\hat{X}(\alpha)|^2
\]
1.7 THE SPECTRAL DENSITY FUNCTION

If we consider a stationary stochastic process, or rather a single realization (i.e. $X(t)$) thereof (and w.l.o.g. assume $E(X(t)) = 0 \forall t$), we cannot assume $X(t)$ is periodic and nor can we assume $X(t)$ is absolutely integrable. Thus it would seem we cannot represent $X(t)$ into a Fourier series (since $X(t)$ must either be periodic, or nonperiodic but absolutely integrable over $(-\infty, \infty)$ - see section 1.5 for the latter restriction).

To skirt this problem, simply define another process, $X^*(t)$ say, such that

$$X^*(t) = \begin{cases} X(t) & -\infty < t < T \\ 0 & \text{otherwise} \end{cases} \quad (1.13)$$

Then we may write

$$X^*(t) = \int_{-\infty}^{\infty} g(w) e^{iwt} dw$$

where

$$g(w) = \int_{-\infty}^{\infty} X^*(t) e^{-iwt} dt$$

$$= \int_{-\infty}^{\infty} X(t) e^{-iwt} dt$$

Since $X(t)$ may or may not possess a Fourier integral, the (as $\int_{-\infty}^{\infty}$) of $|g(w)|^2$ does not exist. But the total energy off by $X(t)$ in the interval $(-\infty, \infty)$ is equal to

$$\int_{-\infty}^{\infty} X^2(t) dt$$
(By the basic laws of electrical circuit theory - Priestley(1981))

\[ \int x^2(t) \, dt = \int |g(w)|^2 \, dw. \]

However, under suitable conditions, the limit (as \( \omega \to \omega \)) of \( |g(w)|^2 / 2\pi \)
may be finite (c.f.)

If this limit exists, it will only be for the specific realization
of \( X(t) \) considered. In order to construct some quantity represenative of the whole stochastic process, consider rather the
average of \( |g(w)|^2 / 2\pi \) over the different realizations. That
we define

\[ S(w) = \lim \left\{ \frac{1}{2\pi} \int |g(w)|^2 \, dw \right\} \quad \text{way} \]

(1.10)

When \( S(w) \) exists, the average contribution to the total
power from components in \( X(t) \), with frequencies between \( w \) and
\( w + dw \), is \( S(w) \) in Wts. per cycle.

Definition 3

\[ H(w) = \lim \left[ \frac{1}{2\pi} \int \frac{d|g(w)|^2}{dw} \right] \]

This called the (power) spectral density
function (power part) of \( X(t) \).

If \( H(w) = \int H(w) \, dw \)

then \( h(w) \) is the average contribution to the total power from all
components with frequencies \( \frac{w}{2} \). Then \( h(w) \) exists, \( \frac{d}{dw} H(w) = h(w) \).

(Note: If \( X(t) \) is deterministic with period \( T \), then total energy
over \( [\alpha, \beta] \) = \( \int x^2(t) \, dt \).

\[ (1.10) \]

\[ S(w) = \lim \left\{ \frac{1}{2\pi} \int |g(w)|^2 \, dw \right\} \quad \text{way} \]

(1.10)
If we assume $X(t)$ has the Fourier representation given by (1.8), then

$$
\int_{-\pi}^{\pi} X^2(t) dt = \left( \frac{1}{2} a_0^2 + \sum_{k=1}^{\infty} (a_k^2 + b_k^2) \right)
$$

Define

$$
e^2_k = \frac{1}{2} (a_k^2 + b_k^2)
$$

then total energy over $(-\pi, \pi) = 2\pi \sum_{k=0}^{\infty} e^2_k$

and the total energy given off per unit time interval

$$
= \sum_{k=0}^{\infty} e^2_k
$$

(A plot of $e^2_k$ against $k$ gives the discrete power spectrum). So we have a breakdown of the energy into contributions made by particular terms.

1.8 SUMMARY

In this chapter we have introduced the concepts of stationarity and two important functions - the spectral density function (sdf) and the autocovariance function (acvf). The importance of these two functions will be discussed in more detail in the next chapter.

We have also seen how any process (whether random or deterministic, periodic or nonperiodic) may be expressed in terms of a Fourier series representation i.e. a sum (or integral) of sine and cosine functions, evaluated over a range of frequencies. We can compare the power of different frequencies by plotting the Fourier transform of the series.

This plot (or power spectrum) gives an idea of the contribution of certain sine and cosine functions (terms) to the overall process.
CHAPTER 2: THE WIENER-KHINTCHINE THEOREM AND THE SPECTRAL DENSITY FUNCTION

In the previous chapter we saw two seemingly unrelated functions, the autocovariance function (acvf) and the spectral density function (sdf). In this chapter, we shall prove the existence of the most important relationship between the sdf and the acvf. This result is one of the most important (if not the most important) results used when analysing time-series in the frequency domain.

Further results concerning the sdf and acvf will be given, as well as properties and estimation procedures. It must be borne in mind that the objective of all this theory is firstly to help us understand the concepts involved and secondly to take this understanding and these concepts and apply them to our observed time-series and hence formulate a model which "describes" the time-series.

2.1 RELATING THE SDF TO THE ACVF

The relationship between the acvf and sdf can be expressed in the following theorem

**Theorem 6**

If \( X(t) \) is a (zero-mean) stationary process (where \( t \) is a continuous time variable) with sdf \( h(w) \) and acvf \( \rho(\tau) \) then

\[
h(w) = \frac{1}{2} \int e^{-j\omega \tau} \rho(\tau) d\tau
\]

(2.1)

Definitions 11 and 13 respectively
Proof To prove this theorem we need to make use of a lemma given below.

Lemma 1: If $f_1(t)$ and $f_2(t)$ are real-valued functions with Fourier transforms and

$$F_1(w) = \int_{-\infty}^{\infty} e^{-iwt} f_1(t) dt$$

and

$$F_2(w) = \int_{-\infty}^{\infty} e^{-iwt} f_2(t) dt$$

then $F_1(w) F_2(w) = \int_{-\infty}^{\infty} e^{-iwt} k(t) dt$

where $\overline{F(w)}$ denotes the complex conjugate of $F(w)$ and

$$k(t) = \int_{-\infty}^{\infty} f_1(x) f_2(x-t) dx$$

(For proof of this lemma, see Priestley (1981), pg. 211).

As a result of this lemma, if $f_1(t) = f_2(t)$, then

$$F_1(w) F_2(w) = \int_{-\infty}^{\infty} e^{-iwt} k(t) dt$$

where

$$k(t) = \int_{-\infty}^{\infty} f_1(x) f_1(x-t) dx$$

Applying (2.2) to (1.11), gives us

$$g(w) = \int_{-\infty}^{\infty} e^{-i\omega v} \left\{ \int_{-\infty}^{\infty} X^*(u) \frac{X(u-v)}{2^2} du \right\} dv$$

where $X^*(t)$ is as defined in (1.13) and $g(w)$ as in (1.14)

So

$$\frac{g(w)^2}{2^2} = \frac{1}{2^2} \int_{-\infty}^{\infty} e^{-i\omega v} (v) dv$$
where \[ x(v) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(u) e^{-iuv} du. \]

Thus,

\[ S(v) = \frac{1}{\pi} \int_{-\infty}^{\infty} \left| x(u) \right|^2 e^{-iuv} du = \frac{1}{\pi} \int_{-\infty}^{\infty} \left| x(u) \right|^2 e^{-iuv} du \]

(by (1.13)).

But,

\[ x(u) = \begin{cases} \frac{1}{2}, & |u| < |v| - \frac{1}{2} \\ 0, & |u| > |v| - \frac{1}{2} \end{cases} \]

(by the definition of (1.13)).

Considering \( |v| < 2\pi \) and \( |v| = 2\pi \) separately,

\[ S(v) = \begin{cases} \frac{1}{2}, & |v| < 2\pi \\ 0, & |v| = 2\pi \end{cases} \]

(since \( x(u) \) is zero-mean stationary and by the definition of \( x(v) \) in section 1.4).

hence,

\[ S(v) = \frac{1}{\pi} \int_{-\infty}^{\infty} \left| x(u) \right|^2 e^{-iuv} du \]

(by (2.31)).

To evaluate this limit, we consider the limiting form of \( (1 - \frac{v}{2\pi})^2 \) as \( v \to \pm \infty \) it tends to 1 as \( v \to \pm \infty \) for all fixed \( \xi \).

So \( (1 - \frac{v}{2\pi})^2 \) is fast enough for its Fourier transform to exist, we get the result.

This theorem gives us a very important link. It provides the condition necessary for \( \hat{x}(v) \) to exist. \( |x(t)| \) should be such
where
\[ g(v) = \frac{1}{2\pi} \int X(u)X(u-v)du \]

Thus
\[ h(w) = \frac{1}{2\pi} \left( \int \left( \frac{g(v)}{2\pi} \right)^2 dv \right) = \frac{1}{2\pi} \int \left( \frac{1}{2\pi} \int e^{-i\omega v} \phi(v) dv \right) dv \]  
(2.3)

(by (1.13))

But
\[ \int \frac{1}{2\pi} \left( \int X(u)X(u-v)du \right) dv = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\omega v} \psi(v) dv \]
(1.15)

(by the definition of (1.13))

Considering \( |v| \leq 2\pi \) and \( |v| \geq 2\pi \) separately,
\[ E(\phi(v)) = \begin{cases} (v)(1-\frac{|v|}{2\pi}) & |v| \leq 2\pi \\ \phi(v) & |v| > 2\pi \end{cases} \]

(since \( X(t) \) is zero-mean stationary and by the definition of \( \phi(v) \) in section 1.4)

hence
\[ h(w) = \frac{1}{2\pi} \left[ \int_{-\infty}^{2\pi} e^{-i\omega v} \psi(v) dv \right] \]  
(by (2.3))

To evaluate this limit, we consider the limiting form of \( \left( \frac{1}{2\pi} \right)^2 \) as \( \omega \to \infty \) and \( \phi(v) \to 0 \) for all fixed \( v \)

So if \( \phi(v) \to 0 \) fast enough for its Fourier transform to exist,

we get the result:

This theorem gives us a very important tool. It provides

the condition necessary for \( h(w) \) to exist - \( \phi(v) \) should be such
that its acvf has a Fourier transform. This Fourier transform exists if \( (v) \) is absolutely integrable (see section 1.6), i.e. (more formally)

**Theorem 7**

\[
h(w) \text{ exists } \forall w \text{ if } \int_{-\infty}^{\infty} f(t) dt < \infty.
\]

Note that if \( X(t) \) is a real-valued process then (2.1) reduces to

\[
h(w) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \cos(w) \gamma(t) dt
\]

(since \( h(w) \) is an even function of \( w \)) and similarly

\[
\gamma(t) = \int_{-\infty}^{\infty} 
\]

(since if \( A(t) \) is continuous at 0 (and hence, everywhere), we may write

\[
\gamma(t) = \int_{-\infty}^{\infty} e^{iwt} h(w) dw
\]

by (1.14) - since \( X(t) \) is absolutely integrable).
Thus knowledge of either $h(w)$ or $\gamma(t)$ implies knowledge of the other.

If we define

$$H(w) = \int h(\theta) d\theta$$

then

$$H(w) = \int_{-\infty}^{\infty} \frac{1}{2\pi} \cos(\theta t) \gamma(t) dt d\theta$$

if $X(t)$ is real-valued (which is the case we shall consider in this study). But $h(w)$ is an even function (since $\gamma(-t) = \gamma(t)$) and $\gamma(t)$ is also an even function, so

$$H(w) = \frac{1}{2} \int_{-\infty}^{\infty} \sin(wt) \gamma(t) dt \quad \forall w > 0$$

Since $H(w) - H(w_j) = \frac{1}{2\pi} \int h(\theta) d\theta$

$$= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{-1\omega^2 - \omega \omega_j}{-1\omega^2 - 1\omega_j} \gamma(t) dt$$

(assuming we can interchange the order of integration)
Now \( H(0) = \frac{\sigma^2}{2} \) (since \( \gamma(0) = \int h(w)dw = \frac{\sigma^2}{2} \))

but \( h(w) \) is an even function so \( h(w) = h(-w) \) and \( H(w) = \frac{\sigma^2}{2} \int \frac{e^{-iwT}}{1+iw} \gamma(t)dt \)

Replace \( \sin(t) \) by \( \frac{e^{it} - e^{-it}}{2i} \) to get result.

It also follows that

\[
\begin{align*}
(i) & \quad H(w) = \frac{\sigma^2}{2} \gamma(0) = \int \gamma(w)dw \\
(ii) & \quad H(-w) = 0
\end{align*}
\]

**Definition 14**

The normalized sdf (or nsdf), \( f(w) \), is defined by

\[
f(w) = h(w) = \frac{1}{2} \int \frac{e^{-iwT}}{1+iw} \gamma(t)dt
\]

As a result of the form of \( h(w) \), it has the following properties

\[
\begin{align*}
(i) & \quad \int f(w)dw = 1 \quad \text{i.e. } f(w) \text{ has the form of a pdf (also using the next property)} \\
(ii) & \quad f(w) > 0 \quad \forall w \\
&s (\text{since } |g(w)|^2 > 0 \quad (g(w) \text{ as in (1.14)}) \\
&\quad = h(w) > 0 \\
&\quad = f(w) > 0
\end{align*}
\]

(iii) If \( X(t) \) is real-valued,

\[
f(w) = f(-w) \\
(iv) f(w) = \frac{1}{2\pi} \int e^{-iwT} \gamma(t)dt
\]

where \( \gamma(t) \) is the acrf (autocorrelation function)

\[
\text{(hence } \gamma(t) = \int e^{i\omega} f(w)dw \text{ )}
\]

(2.6)
(v) \[ F(w) = \int_{-\infty}^{w} f(\theta) d\theta \quad \text{so} \]

\[ f(w) = \frac{d}{dw} F(w) \quad \text{(if it exists)} \quad (2.12) \]

and (a) \( 0 < F(w) < \infty \)
(b) \( F(w) \) is a nondecreasing function of \( w \)

(vi) If \( X(t) \) is real-valued

(a) \[ f(w) = \frac{1}{\pi} \int_{-\infty}^{\infty} \cos(wt) \sigma(t) dt \quad (2.13) \]
(b) \[ C(\tau) = \int_{-\infty}^{\infty} \cos(w\tau) f(w) dw \quad (2.14) \]
(c) \[ F(w) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{\sin(w\tau)}{w} f(w) dw + \frac{1}{2} \quad (2.15) \]

(from the result on the previous page)

In this section we have seen the very important relationship that exists between the acvf and the sdf and we have also provided a condition sufficient for \( h(w) \) (and hence \( f(w) \)) to exist (namely that \( f(\tau) \) is absolutely integrable). The only remaining thing to be proved is that \( h(w) \) (or \( f(w) \)) always exists for a stationary process. This is proved in the next section in the Wiener-Khintchine theorem.

2.2 THE WIENER-KHINTCHINE THEOREM

It is a very important theorem and is used to establish the

that if a process is stationary, \( f(w) \), the nsdf, exists provided \( F(w) \) is absolutely continuous or equivalently that \( f(\tau) \) (the acrf) satisfies the condition that

\[ \int_{-\infty}^{\infty} f(\tau) d\tau = 1 \]

26

Absolutely integrable).

If \( f(x) \) does not exist, we are still able to express \( \mathcal{C}(T) \) i.t.o.

\[
\mathcal{C}(T) = \int_{-\infty}^{\infty} e^{i\omega T} dF(w)
\]

which is termed a Fourier-Stieltjes (Wiener 1930)) transform

and is defined even when \( F(w) \) is not differentiable everywhere.)

More formally

**Theorem 3 (Wiener-Khintchine (W-K) theorem)**

A necessary and sufficient condition for \( \mathcal{C}(T) \) to be the acrf of some stochastically continuous process \( X(t) \) (see appendix A1), is that there exists a function \( F(w) \) having the properties of a distribution function on \((-\infty, \infty)\) such that for all \( T, \mathcal{C}(T) \) may be expressed in the form

\[
\mathcal{C}(T) = \int_{-\infty}^{\infty} e^{i\omega T} dF(w)
\]

**Proof**

(a) **Necessity**

A theorem by Bochner (1936) states that any positive semi-

Definite function, which is continuous everywhere, must have a Fourier-Stieltjes transform of the form (2.16), with \( F(w) \) having the properties of a distribution function. \( \mathcal{C}(T) \) is continuous by the assumption that \( X(t) \) is stochastically continuous at \( t = t_0 \).

\( q(r) \) is positive semi-definite in the sense that for any time points \( r_1, \ldots, r_n \) and real \( Z_1, \ldots, Z_n \),

\[
\sum_{i=1}^{n} \sum_{j=1}^{n} q(r_i - r_j)Z_i Z_j \geq 0
\]

for any function
\[ \lim_{t \to t_0} \mathbb{E} \left( (X(t) - X(t_0))^2 \right) = 0 \]

- see appendix A1 for a definition of \( \lim \) as well as for other stochastic limiting operations) and \( (\cdot) \) is positive semi-definite by defn. 12, hence the W-K theorem is a special case of Bochner's theorem.

A restricted form of this result is shown in theorem (section 2.1) and we can consider the more general... Using the proof of theorem 8, write

\[ \mathbb{E} \left( \frac{g(w)^2}{2 \pi \sigma^2} \right) = \frac{1}{2 \pi} \int_{-\infty}^{\infty} x(v) e^{-ivw} dv \]  

(2.17)

where

\[ \phi(v) = \begin{cases} v^2 \left[ 1 - \frac{|v|}{2^2} \right] & v < 2^2 \\ 0 & v \geq 2^2 \end{cases} \]

Let \( f(w) = \mathbb{E} \left( \frac{g(w)^2}{2 \pi \sigma^2} \right) \) and multiply both sides of (2.17) by \( e^{ivw} \). Integrating from \( -\infty \) to \( \infty \) gives

\[ (1 - \frac{v^2}{2^2}) f(w) \mathbb{E} \left( \frac{g(w)^2}{2 \pi \sigma^2} \right) dw = \frac{1}{2 \pi} \int_{-\infty}^{\infty} |\sin(\frac{1}{2} (v-t))| \frac{\sin(\frac{1}{2} (v-t'))}{\sin(\frac{1}{2} (v-t))} dv \]

(since \( \int_{-\infty}^{\infty} (1 - \frac{v^2}{2^2}) g(w)^2 dw = \frac{\pi}{2} \left( \frac{1}{2^2} \right) \))

Now \( f(w) \) is nonnegative for all \( v \), so if

\[ (1 - \frac{v^2}{2^2}) f(w) \]

is suitably scaled, it may be regarded as a pdf over the range \((-1,5)\). As a result, the LHS of (2.18) has the properties of...
a (sized) characteristic function.

As \( t \to 0 \),

\[
\frac{x}{2} \left( \frac{\sin \frac{1}{2} (x-t)}{\sin \frac{1}{2} (x)} \right) \to \frac{1}{2} (\delta(x) - \delta(x-t))
\]

behaves like a Dirac delta function, \( \delta(x-t) \).

If \( f(t) \) is any function continuous at \( t = 0 \), the Dirac delta function, \( \delta(t) \), is such that

\[
\int_{-\infty}^{\infty} \delta(t) f(t) \, dt = f(0)
\]

Outline proof. Since the Dirac delta function \( \delta(x) \) is usually defined by

\[
\delta(x) = \begin{cases} 0 & x \neq 0 \\ \infty & x = 0 
\end{cases}
\]

such that \( \int_{-\infty}^{\infty} \delta(x) \, dx = 1 \) (we then need to show

\[
\lim_{t \to 0} \frac{\sin \frac{1}{2} (x-t)}{\frac{1}{2} x} = \delta(x)
\]

1-1. \( \lim_{x \to 0} \frac{2\sin^2 \frac{x}{2}}{x^2} = \delta(0) \)

For \( x \neq 0 \), this is certainly true (since the sine function is bounded); for \( x = 0 \), it may be shown that

\[
\lim_{x \to 0} \frac{2\sin \frac{1}{2} x}{x} = \delta(0)
\]
So as $t \to \infty$, the RHS of (2.18) converges (uniformly) to $\lambda(t)$ (provided $\lambda(t)$ is continuous).

Hence $\lambda(t)$ is proportional to the characteristic function and since $\lambda(0) = \mu(0) = 1$, $\lambda(t)$ is (exactly) a characteristic function.

Also, as $t \to \infty$, $\lambda(t)$ converges (uniformly) to $\lambda(0)$ and so $\lambda(t)$ is also a characteristic function. Hence there must exist some distribution function $F(w)$ which is such that $\lambda(0)$ is its Fourier-Stieltjes transform.

(b) Sufficiency

Let $Y$ be a random variable having $F(y)$ as its distribution function satisfying (2.16) and let $Z$ be a random variable having a Uniform $(-\pi, \pi)$ distribution (independent of $Y$).

Define

$$X(t) = e^{i(Z + Yt)}$$

(2.19)

$$E(X(t)) = E(e^{iZ})E(e^{itY})$$

but $E(e^{iZ}) = 0$

$$E(X(t)) = 0 \quad \forall t$$

and $V(X(t)) = E[|X(t)|^2]$

$$= \frac{2}{\pi} \quad \text{(by defn.)}$$

(since $|X(t)|^2 = \cos^2(Z + Yt) + \sin^2(Z + Yt) = 1$)

Also,

$$\lambda(0) = E(e^{iZ}) = E((Z + Yt) - Yt)$$

and
So $X(t)$ defined by (2.19) has the given function $\phi(\tau)$ as its acrfs.

2.3 DISCRETE PROCESSES

Without actually having stated it, the processes considered so far in this chapter have all been continuous ones i.e. $X(t)$ has been defined for a continuous-time variable $t$. However our main interest lies in discrete time-series and hence processes which are defined only for integer $t$ values i.e. $X(t)$, $t = 0, 1, 2, \ldots$. Denoting these processes by $X_n$, an analogue of the Wiener-Khintchine theorem is required (since we can no longer talk in terms of integrals and continuous acrfs', but rather we are forced to consider summations and discrete acrfs'). This analogue is known as Wold's theorem.

Theorem 9 (Wold's theorem)

A necessary and sufficient condition for the sequence $\phi(r); r = 0, 1, \ldots$ to be the acrf for some discrete time process $X_n, t = 0, 1, \ldots$, is that there exist a function $F(w)$ having the properties of a distribution function on $(-\infty, \infty)$ such that

$$\phi(r) = \int_{-\infty}^{\infty} e^{2\pi irw} F(w) \, dw \quad r = 0, \pm 1, \ldots \quad (2.20)$$
Proof

(a) Necessity

Plot \( D(r) \) against \( r \) and join consecutive points by straight lines; this will give \( x(\cdot) \), say, \( V \), and in particular

\[
x(\tau) = (s+1-\tau)(\tau-s)(s+1) \quad \text{where } s < \tau < s+1
\]

and \( x(-\tau) = x(\tau) \).

Then \( x(\cdot) \) is continuous everywhere and Priestley (1963) has shown that there exists a stationary continuous-time process, which has \( x(\cdot) \) as its acf. Hence by the W-K theorem, there exists a nondecreasing function, \( F^*(w) \) say, such that

\[
x(\tau) = \int_{-\infty}^{\infty} e^{iw\tau} dF^*(w).
\]

This is true \( V \) and so is certainly true when \( \tau \) is an integer, \( r \) say,

\[
D(r) = \int_{-\infty}^{\infty} e^{i\pi r} dF^*(w) \quad \text{for } r = 0, \pm 1,\ldots
\]

hence

\[
D(r) = \frac{1}{2\pi} \int_{2\pi r}^{2\pi(r+1)} e^{i\pi r} dF^*(w)
\]

since \( e^{i(2\pi r + 2\pi^2 r^2)} = e^{i\pi r} \).
Let \( \frac{1}{3} dF(w) = \frac{1}{3} dF(w + 2\pi) \) (with \( F(-\pi) = 0 \)) and then (2.20) follows. The \( (b) \) sufficiency condition is similar to that of the W-K theorem.

Comparing (7.20) with (1.3) and (1.6) and assuming \( F(w) \) is differentiable everywhere (thus \( f(w) = \frac{d}{dw} F(w) \)) then

\[
\hat{c}(r) = \int_{-\pi}^{\pi} e^{iwr} f(w) \, dw.
\]  

(2.21)

\( Z = \) is the coefficient of \( e^{iwr} \) in a Fourier series expansion of \( f(w) \), hence

\[
f(w) = \sum_{r=1}^{\infty} \hat{c}(r) e^{iwr}, \quad -\pi < w < \pi
\]  

(2.22)

Note that if \( X_t \) is real-valued, then

\[
f(w) = \frac{1}{2\pi} - \frac{1}{\pi} \sum_{r=1}^{\infty} \hat{c}(r) \cos(rw)
\]  

(2.23)

and

\[
F(w) = \int_{-\pi}^{\pi} f(t) \, dt
\]

\[
= \frac{1}{2\pi} - \frac{1}{\pi} \sum_{r=1}^{\infty} \hat{c}(r) \sin(rw), \quad -\pi < w < \pi
\]  

(2.24)

Thus if we have a (stationary) discrete time-series we can compute the theoretical acrf or the theoretical sdf of the process, provided we have knowledge of one or the other. The usefulness of this technique will be shown at a later stage.
2.4 ESTIMATION OF THE ACVF (AND HENCE ACRF AND SDF)

In general, we only have a finite realization of the time series, i.e., a sample from a stationary process \( \{X_t\} \) of size \( N \), so suppose this sample can be represented by \( x_1, x_2, \ldots, x_N \). Now, since we only have a sample, we cannot compute the theoretical acvf or sdf, but rather only estimates of parts thereof.

Forming the observations \( x_1, x_2, \ldots, x_N \) into (non-independent) pairs

\[
(x_1, x_{r-1}), (x_2, x_{r-2}), \ldots, (x_{N-r}, x_r), \quad r > 0
\]

then in general, these pairs will come from different bivariate distributions. However since \( \{X_t\} \) is (second-order) stationary, all these bivariate distributions will have the same covariance, \( \gamma(r) \) say.

Defining \( \{z_i\} \) to correspond to \( \{x_1, x_2, \ldots, x_{N-r}\} \) and \( \{y_i\} \) to \( \{x_{r+1}, x_{r+2}, \ldots, x_N\} \), then it is possible to estimate \( \gamma(r) \) by

\[
\frac{1}{n} \sum_{i=1}^{n} (z_i - \bar{z})(y_i - \bar{y})(n = N - r)
\]

But it is senseless using two separate estimates \( \bar{z} \) and \( \bar{y} \) since \( \{z_i\} \) and \( \{y_i\} \) both came from the same distribution (assuming second order stationarity) - so estimate \( \bar{z} \) and \( \bar{y} \) by \( \bar{x} \) (the sample mean of \( x_1, x_2, \ldots, x_N \)).

Thus

\[
\hat{\gamma}(r) = \frac{1}{N-r} \sum_{t=1}^{N-r} (x_t - \bar{x})(x_{t+r} - \bar{x})
\]

(2.25)
2.4 ESTIMATION OF THE ACVF (AND HENCE ACRF AND SDF)

In general, we only have a finite realization of the time series, i.e. a sample from a stationary process \( \{x_t\} \) of size \( N \), say.

Suppose this sample can be represented by \( x_1, x_2, \ldots, x_N \). Now since we only have a sample, we cannot compute the theoretical acvf or sdf, but rather only estimates of parts thereof.

Forming the observations \( x_1, x_2, \ldots, x_N \) into (non-independent) pairs,

\[
(x_1, x_{r+1}), (x_2, x_{r+2}), \ldots, (x_{N-r}, x_N)
\]

then in general, these pairs will come from different bivariate distributions. However since \( \{x_t\} \) is (second-order) stationary, all these bivariate distributions will have the same covariance, \( \gamma(r) \) say.

Defining \( \{z_1\} \) to correspond to \( (x_1, x_2, \ldots, x_{N-r}) \) and \( \{y_1\} \) to \( (x_{r+1}, x_{r+2}, \ldots, x_N) \), then it is possible to estimate \( \gamma(r) \) by

\[
\frac{1}{n} \sum_{i=1}^{n} (z_i - \bar{z})(y_i - \bar{y})
\]

\( (n = N - r) \)

But it is senseless using two separate estimates \( \hat{z} \) and \( \hat{y} \) since \( \{z_1\} \) and \( \{y_1\} \) both came from the same distribution (assuming second order stationarity) - so estimate \( \hat{z} \) and \( \hat{y} \) by \( \bar{x} \) (the sample mean of \( x_1, x_2, \ldots, x_N \)).

Thus

\[
\gamma(r) = \frac{1}{8r(N-r)} \sum_{i=1}^{N-r} (x_i - \bar{x})(x_{i+r} - \bar{x})
\]

\( (2.25) \)
Since \( v(r) \) is an even function, it is reasonable to make \( \gamma(r) \) and even function also

\[ i.e. \quad \gamma(-r) = \gamma(r) \quad \forall \text{ integer } r \]

Properties of \( c_r \):

(i) If \( u \) is replaced by \( \bar{x} \) in (2.25) (to give a new estimate, \( c_r \) say)

\[ \text{then } E(c_r^n) = \gamma(r), \quad \forall r \]

(ii) If \( \bar{x} \) is not replaced by \( \bar{u} \), then

\[ E(c_r^n) = \gamma(r) - V(\bar{x}) \]

\[ = \gamma(r) - \frac{2r^2}{N} f(O) \]

Outline proof: if \( \bar{x} \) has sdf \( f(v) \), then

\[ f(v) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \Gamma(r)e^{-ivr} \quad \text{(by definition)} \]

and

\[ \lim_{N \to \infty} \frac{1}{N} \sum_{r=1}^{N-1} (1 - \frac{r}{N}) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \Gamma(r)e^{-ivr} \]

Also,

\[ V\left( \sum_{i=1}^{p} a_i x_i \right) = \sum_{i=1}^{p} \sum_{j=1}^{p} a_i a_j^* \gamma_{ij} \quad \text{where } \gamma_{ij} = \text{Cov}(X_i, X_j) \]

\[ p \text{ any integer } > 0 \]

so

\[ V(\bar{x}) = \frac{2}{N^2} \sum_{r=1}^{N-1} \gamma(r) \]

\[ = \frac{2f(O)}{N} \]

(as \( N \to \infty \))

since
\[ r = c_r \text{ say } (r = 0, \pm 1, \ldots, N-1) \]

Since \( \gamma(r) \) is an even function, it is reasonable to make \( \gamma(r) \) and even function also

\[ \gamma(-r) = \gamma(r) \quad \forall \text{ integer } r. \]

**Properties of \( \gamma(r) \):**

(i) If \( \mu \) is replaced by \( \bar{X} \) in (2.25) (to give a new estimate, \( c_r^* \) say)

then \( E(c_r^*) = \gamma(r) \), \( \forall r \)

(ii) If \( \bar{X} \) is not replaced by \( \mu \), then

\[ E(c_r^*) = \gamma(r) - V(\bar{X}) \]

\[ = \gamma(r) - 2^{r-2} \frac{2}{N} f(0) \]  

(2.27)

**Outline proof:** If \( X_i \) has sdf \( f(x) \), then

\[ f(x) = \frac{1}{2^N} \sum_{r=0}^{N-1} \gamma(r) e^{ixr} \]  
(by definition)

and

\[ \frac{(N-1)}{N} \left(1 - \frac{1}{N}\right)^{(r)} = \sum_{r=0}^{N-1} \gamma(r) = 2^{-f(0)} \]

Also,

\[ V \left\{ \sum_{i=1}^{N} x_i \right\} = \sum_{i=1}^{N} \sum_{j=1}^{N} \sigma_i^2 \sigma_j^2 \text{ where } \sigma_{ij} = \text{cov}(x_i, x_j) \]

\( \forall \text{ any integer } \geq 0 \)

\[ V(\bar{X}) = \frac{2}{N} \sum_{r=0}^{N-1} (N-1)^{2} f(\bar{X}) \]

\[ = 2^{-f(0)} \frac{2}{N} \text{ (as } N \to \infty) \]

since
(a) if \( \lim_{N \to \infty} \left( \frac{1}{N} \sum_{r=1}^{N} \left( 1 - \frac{r}{N} \right) \phi(r) \right) \) is finite

then \( V(X) = 0 \) as \( N \to \infty \) and

(b) if \( X \) has a purely continuous spectrum with \( \mu = \inf \{ \chi \} \) then

\[
\xi(x) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \phi(r)e^{-irx} \, dr
\]

and it may be shown that

\[
\lim_{N \to \infty} \left( \frac{1}{N} \int_{-\pi}^{\pi} \left( 1 - \frac{r}{N} \right) \phi(r) \, dr \right) = \frac{1}{2\pi} \mu(r)
\]

\[= 2\mu(0)\]

Now

\[
\frac{N-1}{N} \left( s_{\frac{1}{N}} - s \right) \mu r_{\frac{1}{N}} \left( r_{\frac{1}{N}} - \hat{r} \right) = \frac{1}{N} \sum_{r=0}^{N-1} \left( \left( x_{\frac{1}{N}} - \hat{r} \right) - \left( \hat{r} - \hat{r} \right) \right) \left( x_{\frac{1}{N}} - r \right)
\]

\[
= \frac{1}{N} \sum_{r=0}^{N-1} \left( \left( x_{\frac{1}{N}} - r \right) - \left( \hat{r} - \hat{r} \right) \right) \left( x_{\frac{1}{N}} - r \right) - \left( \hat{r} - \hat{r} \right) \left( x_{\frac{1}{N}} - r \right)
\]

\[
= \left( (N-1) \mu \right) r_{\frac{1}{N}} + \hat{r} - 1 + (N-1) r_{\left( \frac{1}{N} \right)}^2
\]

hence result.

Another estimate for \( \rho \) is in fact the more widely used one.
\begin{equation}
\frac{\partial^2 \psi}{\partial x^2} + k^2 \psi = 0
\end{equation}

\section{Introduction}

The main reason for using \( a_p \) instead of \( c_p \), is that whereas \( a_p \) is not necessarily positive semi-definite, \( c_p \) always is. This is why we have the opportunity to replace \( \eta \rightarrow 2 \) in \( a_p \) then

\begin{equation}
\eta = \frac{\eta}{N - 1} \quad \text{when } \eta \ll 1
\end{equation}

If \( \eta \) becomes comparable to \( N \), the above is small, and if

\[ \eta \]

and the phase is approximately \( \chi \). But if \( \chi \) has no significant phase, then \( \eta \rightarrow 2 \) as \( \eta \rightarrow 0 \) (by the implication of the Taylor theorem). If \( \eta \) exists \( \eta \) increases \( \eta \rightarrow 0 \) if \( \eta \) is large relative to the rate of change with respect to \( \eta \). Then \( \eta \rightarrow 0 \) as \( \eta \rightarrow N-1 \).

\end{document}
It may also be shown (see appendix A2) that

(a) \( V(c_r') \) is of order \( \frac{1}{N} \) and

(b) \( V(c_r) \) is of order \( \frac{1}{N - |r|} \)

Thus using (a) and (b), as \( r \to N - 1 \), \( V(c_r') \) remains constant

So if \( r \) is small relative to \( N \), there is little difference

between the estimates \( c_r \) and \( c_r' \). However if \( r \) is large relative
to \( N \), the larger bias of \( c_r' \) is compensated for by its smaller

variance. So considering the merit of the positive semidefinite

property, it seems preferable to use \( c_r' \) instead of \( c_r \) as an

estimate of \( \lambda(r) \).

(Jenkins and Watts (1968) conjecture that \( c_r \) generally has a

higher MSE).

2.5 ESTIMATION OF THE ACRF

Since \( \lambda(r) = \lambda(r)(0) \), obvious estimates for \( \lambda(r) \) will be

\[ \lambda_1(k) = \frac{r_k}{c_k', c_0} \]

and

\[ \lambda_2(k) = \frac{r_k}{c_k', c_0} \]

where \( c_k' = c_0 \) \( k = 0, 1, \ldots, \infty(N-1) \)

The preferable estimate (for the same reasons as in the

previous section) is \( r_k' \).

The variance and covariance of acr estimators are given in

appendix A3.
2.6 SUMMARY

In this chapter we have seen the relationship that exists between the acvf and the sdf. Thus knowledge of one implies knowledge of the other (given certain conditions). We have also seen the necessary conditions for the existence of the sdf (or nsdf'). These conditions were given in the Wiener-Khintchine theorem which handles the concept of the spectrum in the continuous-time domain.

For discrete-time processes, a different theorem was needed, namely Wold's theorem, and there again sufficient and necessary conditions were given for a sequence \( \{x(t)\} \) to be the acrf of a discrete-time process \( \{X_t\} \).

Finally, estimates of the acvf and acrf, based on a sample \( x_1, x_2, \ldots, x_N \) (from a discrete-time process), were formulated. The variance and covariances of these estimates are given in appendices A2 and A3.

In the next chapter we shall see some of the practical uses of these tools.
CHAPTER 3: PERIODOGRAM ANALYSIS

3.1 INTRODUCTION

Some of the more important aspects of the theory seen so far can be summed up as follows:

(a) Any periodic function $g(x)$ can be written in terms of a Fourier series i.e.

$$g(x) = \sum_{r=0}^{\infty} \left( a_r \cos\left( \frac{2\pi r x}{h} \right) + b_r \sin\left( \frac{2\pi r x}{h} \right) \right)$$

(b) For any stationary stochastic process with acvf $\gamma(k)$, there exists a monotonically increasing function $F(w)$ such that

$$i^k \gamma(k) = \int e^{iwx} dF(w)$$

If

$$f(w) = \frac{1}{dw} F(w)$$

exists $\forall w$, then

$$i^k \gamma(k) = \int e^{iwx} f(w) dw.$$
Periodogram analysis is involved with estimating $a_k$, $b_k$, and $(w_k)$ in (3.2) i.e. if we have a set of data $x_0, x_1, ..., x_{N-1}$, we would like to write

$$g(t) = x_t, \quad \forall t$$

and then estimate the parameters in representation (3.2).

On the other hand, spectral analysis is concerned with estimating $f(w)$ in (3.3), based on sample estimates of the $f(k)$.

This chapter is devoted to obtaining estimates of the form (3.2) i.e.

$$x_t = \frac{1}{N} \sum_{k=1}^{\infty} \left( a_k \cos(w_k t) + b_k \sin(w_k t) \right)$$

$$t = 0, 1, ..., N - 1$$

In chapter four we shall see the relationship between periodogram analysis and spectral analysis.

3.2 HARMONIC ANALYSIS

The simplest periodic data are of the form

$$x_t = R \cos(wt) \quad (\text{all } t)$$

A sinusoid of frequency $w$ (or period $\frac{2\pi}{w}$) may be written as

$$g(t) = R \cos(wt + \phi)$$

where

$R = \text{amplitude}$

$\phi = \text{phase}$

Now if we consider a daily time-series of 600 observations, say, which when plotted contains 20 equally spaced peaks, we might expect any periodicity to have a period of around
Thus the \( t \)th data point should contain a component of the form
\[
R \cos(\omega t + \phi) \quad \text{where} \quad x = \frac{2t}{30}
\]

A possible model for the data could be
\[
x_t = R \cos(\omega t + \phi) + \epsilon_t \quad t = 0, 1, \ldots, 599
\]
(where \( \epsilon_t \) is experimental error and \( \epsilon_t \sim N(0, \sigma^2) \)

Initially, if \( \omega \) is kept fixed, the unknown parameters are
\( R \) and \( \phi \). For least squares estimation we need to find \( R \) and \( \phi \) to minimize
\[
S(R, \phi, \omega) = \sum_{t=0}^{599} (x_t - R \cos(\omega t + \phi))^2
\]
i.e. the least squares estimators (LSE)

Reparametrizing \( R \cos(\omega t + \phi) \) to the standard linear form gives
\[
A \cos(\omega t) - B \sin(\omega t) \quad \text{(i.e. a transformation in polar coordinates)}
\]
where \( A = R \cos \phi \)
and \( B = R \sin \phi \)

and keeping \( \omega \) = \( \text{fixed} \) and \( \epsilon \) fixed, it is a simple matter to calculate the LSEs of \( A \) and \( B \) and hence \( R \) and \( \phi \)
i.e.
\[
\frac{\partial S}{\partial A} = -2 \sum (x_t - R \cos(\omega t + \phi)) \cos(\omega t + \phi) = 0
\]
\[
\frac{\partial S}{\partial B} = -2 \sum (x_t - R \cos(\omega t + \phi)) \sin(\omega t + \phi) = 0
\]
Equate these two equations to zero and solve simultaneously. Thus

\[ A = \frac{1}{\sqrt{2}} \left[ \cos(\omega t) \sin(\omega t) \right] - \frac{1}{\sqrt{2}} \sin(\omega t) \cos(\omega t) \sin(\omega t) \]  

(3.5)

\[ B = \frac{1}{\sqrt{2}} \left[ \cos(\omega t) \sin(\omega t) \right] - \frac{1}{\sqrt{2}} \cos(\omega t) \cos(\omega t) \sin(\omega t) \]  

(3.6)

where \( \Delta = \cos(\omega t) \sin(\omega t) - \cos(\omega t) \sin(\omega t) \)

Finding \( \varphi \) and \( \delta \) is easy:

\begin{align*}
\varphi &= \text{arctan} \left( -\frac{B}{A} \right) & \text{if } A < 0, B > 0 \\
\varphi &= \text{arctan} \left( \frac{B}{A} \right) & \text{if } A > 0, B < 0 \\
\varphi &= -\frac{\pi}{2} & \text{if } A = 0, B > 0 \\
\varphi &= \frac{\pi}{2} & \text{if } A = 0, B < 0 \\
\varphi &= \text{arbitrary} & \text{if } A = 0, B = 0 \\
\end{align*}

(since \( R \) is nonnegative and the basic equation for \( \varphi \) is \( \tan \varphi = -\frac{B}{A} \))

and \( R = \left( A^2 + B^2 \right)^{\frac{1}{4}} \)  

(3.8)

Useful approximations to these solutions may be found by noting that

\[ \cos(\omega t) \sin(\omega t) = \frac{1}{2} \left[ D_N(2\omega) \cos((N-1)\omega) \right] \]

\[ \cos(\omega t) \cos(\omega t) \sin(\omega t) = \frac{1}{2} \left[ D_N(2\omega) \sin((N-1)\omega) \right] \]

\[ \sin(\omega t) \cos(\omega t) \sin(\omega t) = \frac{1}{2} \left[ D_N(2\omega) \cos((N-1)\omega) \right] \]
where \( D_N(w) = \frac{\sin \left( \frac{Nw}{2} \right)}{N \sin \left( \frac{w}{2} \right)} \) (3.9)

which is a version of the Dirichlet kernel (see Titchmarsh (1939)).

See, for example, Bloomfield (1976).

Note that \( D_N \left( \frac{2k\pi}{N} \right) = 0 \) \( \forall \) integer \( k \neq 0 \) or a multiple of \( N \)

and \( N D_N(w) < \frac{1}{\sin \left( \frac{w}{2} \right)} \)

any terms in the LSE's involving \( D_N \) are, for large \( N \) and \( w \) not too close to zero, always small when compared with \( \frac{N}{w} \).

By omitting such terms, and allowing \( \lambda \) to be nonzero, we obtain

\[ \lambda = \frac{x^T x}{N} \]

\[ \frac{NA}{2} = x^T \cos(wt) \]

\[ \frac{NB}{2} = x^T \sin(wt) \]

Thus

\[ \lambda^* = \frac{x}{\lambda} \] (3.10)

\[ A^* = \frac{1}{N} \sum (x_i - \bar{x}) \cos(wt) \] (3.11)

\[ B^* = \frac{1}{N} \sum (x_i - \bar{x}) \sin(wt) \] (3.12)

Similarly

\[ R^* = \left( A^* + B^* \right)^\frac{1}{2} \] (3.13)

and \( \lambda^* \) is in terms of \( A^* \) and \( B^* \).

Extending this procedure to take \( \omega \) into account, we now need to minimize

\[ S(\omega(w), A(w), B(w), w) \text{ w.r.t. } \omega, A, B \text{ and } w \]

or equivalently minimize
The residual sum of squares (RSS) is
\[
S(\hat{\xi}(\omega), \hat{\theta}(\omega), \hat{\beta}(\omega, \omega)) = \text{RSS}.
\]
and
\[
\text{RSS} = S(\bar{x}, \bar{x}, \bar{x}, \bar{x}, 0)
\]
\[
= S(\bar{x}, 0, 0, 0, \omega) - \frac{N}{2} \left( \bar{x}^2 + \bar{x}^2 \right)
\]
(since the sum of squares of residuals, RSS, may be written
\[
\text{RSS} = \text{sum of squares of (original data - mean)}
\]
\[
- \text{sum of squares associated with frequency } \omega
\]
\[
= \sum_{t=1}^{N} (x_t - \bar{x})^2 - \frac{1}{N} \sum_{t=1}^{N} (x_t - \bar{x}) \cos(\omega t)
\]
\[
- \frac{1}{N} \sum_{t=1}^{N} (x_t - \bar{x}) \sin(\omega t)
\]
\[
- \frac{1}{N} \sum_{t=1}^{N} (x_t - \bar{x}) \sin(\omega t) \cos(\omega t)
\]
\[
= S(\bar{x}, 0, 0, 0, \omega) - \frac{N}{2} \bar{x}^2.
\]

The 'best' value of \( \omega \), is that value which minimizes the RSS, or equivalently, maximizes \( \hat{x}^2 \) (i.e., \( \hat{x}^2(\omega) \)).

If the residuals from the model are plotted, further periodicity may be apparent. If this is so, remove any periodicity from the residuals in exactly the same manner.

In the final form of the model is
\[
x_t = \xi + \sum_{j=1}^{J} (\xi_j \cos(2\pi j\omega t) + \eta_j \sin(2\pi j\omega t)) + \epsilon_t.
\] (3.14)

(\( x_t \) is an integer \( \geq 1 \))
\( t = 0, \ldots, N - 1 \)

4/3 ALIASING.

What is the range of \( \omega \)? Units of frequency are radians per unit time and hence nonnegative; thus \( \omega \geq 0 \).

Can we restrict \( \omega \) further?
Since \( \cos(w) = \cos(-w) \)

and \( -\sin'(w) = \sin(-w) \),

\( w \) and \( -w \) are indistinguishable and are said to be aliases of each other. If the sampling interval of our data is \( 1 \) (usually 1), then the \( t \)th observation is made at time \( t \). Suppose that the data consist of a pure cosine wave \( \cos(wt) \).

As \( w \) increases from 0, the wave oscillates more and more rapidly until at \( w = \frac{\pi}{2} \), we have \( x_t = (-1)^t \) (the most rapid oscillation).

Increasing \( w \) further - say

\[ \frac{\pi}{2} < w < \frac{2\pi}{3} \]

and letting \( w' = \frac{2\pi}{3} - w \),

then

\[ x_t = \cos(w't) = \cos(w't) \]

Similarly, \( \sin(wt) = \sin(w't) \).

So \( w \) and \( w' \) are aliases of each other, and so every frequency outside the range \( 0, \frac{\pi}{2} \) has an alias in this range (termed its principal alias).

It is known as the Nyquist frequency (and equals half the sampling rate).

### 3.4 THE DISCRETE FOURIER TRANSFORM (DFT)

As already noted in section 3.1, by the theory of chapter one it is possible to express any function (periodic or nonperiodic) into a Fourier series (provided the function satisfies the Dirichlet conditions - see section 1.5) So if \( x(t) \) is our function, we may...
Since $\cos(w) = \cos(-w)$

and $-\sin(w) = \sin(-w)$,

$w$ and $-w$ are indistinguishable and are said to be aliases of each other. If the sampling interval of our data is $\frac{T}{2}$ (usually 1), then the $t^{th}$ observation is made at time $t_0$. Suppose that the data consist of a pure cosine wave i.e.

$$\cos(wt_5) = x_t$$

As $w$ increases from 0, the wave oscillates more and more rapidly until at $w = \frac{\pi}{T}$, we have $x_t = (-1)^t$ (the most rapid oscillation).

Increasing $w$ further - say

$$\frac{\pi}{T} < w < \frac{2\pi}{T}$$

and letting $w' = \frac{2\pi}{T} - w$

then

$$x_t = \cos(wt_5)
= \cos(w't_5)$$

Similarly, $\sin(wt_5) = \sin(w't_5)$

So $w$ and $w'$ are aliases of each other, and so every frequency outside the range $0, \frac{\pi}{T}$ has an alias in this range (termed its principal alias).

$\frac{\pi}{T}$ is known as the Nyquist frequency (and equals half the sampling rate).

3.4 THE DISCRETE FOURIER TRANSFORM (dFT)

As already noted in section 3.1, by the theory of chapter one it is possible to express any function (periodic or nonperiodic) i.e.

a Fourier series (provided the function satisfies the Dirichlet conditions - see section 1.5) So if $g(t)$ is our function, we may
write

\[ g(t) = \sum_{k=1}^{\infty} \left( a_k \cos(w_k t) + b_k \sin(w_k t) \right) \] say.

Now this can be written in the computationally more convenient form

\[ \sum_{k=-\infty}^{\infty} J_k e^{i \omega_k t} \] (see section 1.1)

where \( \omega_k = \frac{2\pi k}{h} \) (if our function has period \( h \)) and

\[ J_k = \frac{1}{2} (a_k - ib_k) \]

\[ J_{-k} = J_k^* \] the complex conjugate.

How do we estimate \( a_k \) and \( b_k \)?

Well, in sections 1.5 (proof of Fourier's theorem) and 1.6 (the nonperiodic case) it was shown that irrespective of whether \( g(t) \) is periodic or nonperiodic,

\[ J_k = \frac{1}{h/2} \int_{t-\frac{h}{2}}^{t+\frac{h}{2}} g(t)e^{-i \omega_k t} \ dt \] (3.16)

(if \( g(t) \) has period \( h \))

and

\[ J_k = \int_{-\infty}^{\infty} g(t)e^{-i \omega_k t} \ dt = J(\omega_k) \] (3.17)

if \( g(t) \) is nonperiodic)
Suppose we assume \( g(t) \) is periodic. This makes more sense, since we shall hopefully be able to devise some test to determine whether the contribution of terms associated with \( w_k \) is significantly different from zero; if all these contributions are not significant, then we may conclude \( g(t) \) is nonperiodic.

Furthermore suppose the period \( h = 2 \) then by the definition of (3.15) and also by section 1.5

\[
\begin{align*}
a_k &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(t) \cos(kt) \, dt \quad k = 0, 1, 2, \ldots \\
b_k &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(t) \sin(kt) \, dt \quad k = 1, 2, \ldots
\end{align*}
\]

(and \( g(t) = x \quad \forall t \))

Now suppose our observed time-series is only defined at \( 2N \) (for computational convenience) equally spaced points. Define

\[
t_k = \frac{k\pi}{N} \quad (k = 0, 1, \ldots, 2N - 1 \text{ say instead of } k = 1, 2, \ldots, 2N)
\]

for convenience.

\[
g(t_k) = g\left(\frac{k\pi}{N}\right)
\]

Rewriting \( J_k \) and \( J_{-k} \) i.e. (1.5) (expressing the exponential terms into cosine and sine functions) and multiplying both sides of (3.19) by \( e^{i\omega t_k} \) and summing over \( k \), we obtain
\[ \sum_{k=0}^{2N-1} i^k e^{it \theta_k} g(t_k) = \frac{1}{N} \sum_{k=0}^{N-1} J_k e^{i(N-1)k} + \frac{1}{2^N} (-1)^k e^{i(N-1)k} \]

However the last term in (3.20) vanishes since it is a geometric sequence and equals

\[ \frac{a_N}{2} \left( 1 - e^{-i (2\pi)/N} \right) \]

and \( e^{-i \pi} = 1 \) when \( \pi \) is an integer multiple of \( 2\pi \).

Also, if \( w_j = w \) say

\[ \sum_{k} e^{-i \omega \theta_k} = 0 \quad \text{if} \quad \omega = 0 \quad \text{(using (3.20a))} \]

so

\[ \sum_{k} e^{-i \omega \theta_k} g(t_k) = \frac{1}{N} \sum_{k} J_j = 2N(J_j) \]

i.e.

\[ J_j = \frac{1}{2N} \sum_{k} e^{-i \omega \theta_k} g(t_k) \quad \text{since} \quad \omega \theta_k \quad \text{since} \quad \omega \theta_k \]

and hence

\[ a_j = \frac{1}{N} \cos \left( \frac{k \omega}{N} \right) g(t_k) \quad j = 0, \ldots, N-1 \]

\[ b_j = \frac{1}{N} \sin \left( \frac{k \omega}{N} \right) g(t_k) \quad j = 1, \ldots, N-1 \]

where \( b_j = 0 \)

and \((-1)^{N-a_j} = a_j + 2(a_1 - a_2 + \ldots + (-1)^{j-1} a_j) + \ldots + (-1)^{N-a_j - 1} \quad \text{(by definition of (3.15))} \)

i.e.

\[ J_j = \frac{1}{2N} \sum_{k} e^{-i \omega \theta_k} g(t_k) \]
Thus if our observed time series is \( x_0, x_1, \ldots, x_{N-1} \) and

\[
g(t) = x_t \quad \text{then defining}
\]

\[
a_j = \frac{2}{2N} \sum_{k=0}^{N-1} g(t_k) \cos\left(\frac{2\pi j t_k}{N}\right)
\]

\[
b_j = \frac{2}{2N} \sum_{k=0}^{N-1} g(t_k) \sin\left(\frac{2\pi j t_k}{N}\right)
\]

\[
a_N = \frac{1}{2N} \sum_{k=0}^{N-1} g(t_k) (N-1) \n^2
\]

\[
b_N = 0
\]

and if \( N \) even then

\[
a_N = \frac{1}{2N} \sum_{k=0}^{N-1} g(t_k) (N-1) \n^2
\]

\[
b_N = 0
\]

where \( \omega_j = 2\pi j/N = j\text{ Fourier frequency} \)

then

\[
x_t = a_0 + \sum_{j=1}^{N/2} \left( a_j \cos\left(\frac{2\pi j t}{N}\right) + b_j \sin\left(\frac{2\pi j t}{N}\right)\right)
\]

\[
+ (N-1)^2 a_N
\]

(the last term appears only if \( N \) even)
3.4.1 NOTES

(i) (3.29) can be rewritten as

\[ x_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n e^{j \omega t} \]  

(3.30)

(ii) \( J_{-j} \) is the complex conjugate of \( J_j \).

(iii) \( J_0 \ldots J_{N-1} \) is called the discrete Fourier transform of \( x_0 \ldots x_{N-1} \).

(iv) The discrete Fourier transform at any frequency \( \omega \) is defined by

\[ J(\omega) = \frac{1}{N} \sum_{n=0}^{N-1} x_n e^{-j \omega t} \]

(3.31)

thus

\[ J(\omega) = J^*(\omega) \]

(v) Writing

\[ x_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n e^{j \omega t} \]

and

\[ R_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n e^{-j \omega t} \]

where \( R_k \) is as defined in (3.13)

(vi) The periodogram is often defined by

\[ (\omega) = \frac{1}{N} R_k^2 \]

The use of the periodogram will be discussed more fully at a later stage.

(vii) If \( x_0 \ldots x_{N-1} \) is a periodic series with period \( h \) and

\[ x_n = x_{n+k} \text{ for some integer } k, \text{ then, by definition} \]

\[ x_k = \frac{1}{h} \sum_{\ell=0}^{h-1} x_{\ell+k} e^{-j \frac{2\pi \ell}{h}}, \quad \ell = 0, \ldots, h - 1 \]

and \( |x_k| \) is called
\[ J_j = \begin{cases} q & j = k \ell \\
0 & \text{otherwise} \end{cases} \quad (k \text{ an integer}) \]

i.e. the transform vanishes except at the frequency \( \omega = \frac{2\pi}{b} \) and its multiples:

(viii) Leakage

Consider the following situation:

suppose \( x_t = \cos(\omega t + \phi) \quad t = 0, \ldots, N - 1 \)

\[ x_t = \frac{1}{2} \left( e^{i(\omega t + \phi)} + e^{-i(\omega t + \phi)} \right) \]

Since \( e^{i\phi} \) is just a scaling factor (i.e. constant), it is only necessary to find the Fourier transform of \( e^{i\omega t} \)

Let \( x_t = z_t + y_t \quad \forall t \)

where \( z_t = \left( \frac{1}{2} e^{i\phi} \right) e^{i\omega t} \)

and \( y_t = \left( \frac{1}{2} e^{-i\phi} \right) e^{-i\omega t} \)

Now \( J_j = \frac{1}{N} \sum_j x_t e^{-i2\pi j \frac{t}{N}} \quad \text{(by definition)} \)

\[ = \frac{1}{N} \left( z_t e^{-i2\pi j \frac{t}{N}} + y_t e^{i2\pi j \frac{t}{N}} \right) \]

\[ = J_{z;j} + J_{y;j} \quad \text{N.A.V.} \]

Now it may be shown (see, for example, Bloomfield (1976)) that
$$\cos(\lambda_i) = \cos \left( \frac{(N-1)\lambda_i}{2} \right) \frac{\sin(\frac{N}{2})}{\sin(\frac{\lambda_i}{2})}$$

(since
$$e^{i\lambda_i} = e^{i(N-1)\lambda_i/2} = e^{i\lambda_i/2} - e^{-i\lambda_i/2}$$

and similarly that

$$\sum_{n=0}^{N-1} \sin^2 t = \sin \left( \frac{(N-1)t}{2} \right) \frac{\sin(\frac{N}{2})}{\sin(\frac{t}{2})}$$

Thus, after manipulation, it may be shown that

$$\sum_{n=0}^{N-1} \frac{\sin(\frac{(N-1)\lambda_i}{2})}{\sin(\frac{\lambda_i}{2})} = \frac{\sin(\frac{\lambda_i}{2})}{\sin(\frac{(N-1)\lambda_i}{2})}$$

And

$$\sum_{n=0}^{N-1} \frac{\sin(\frac{(N-1)\lambda_i}{2})}{\sin(\frac{\lambda_i}{2})} = \frac{\sin(\frac{\lambda_i}{2})}{\sin(\frac{(N-1)\lambda_i}{2})}$$

where
$$x^{(1)} = x^{(2)} = \cdots$$
$$x^{(2)} = \cdots$$
Now if \( w \) is itself a Fourier frequency, \( w_k \) say, then \( J_j \) is zero when \( j \neq k \) and is nonzero for \( j = k \) (in fact it equals \( c_1^j + c_2^j \. cos \frac{j}{w} \).

If \( w \) is not a Fourier frequency then all the \( J_j \) are nonzero.

The appearance of nonzero terms in the transform is due to a sinusoid of a different frequency — this is defined to be 'leakage'. Fourier analysis (or periodogram analysis) is carried out in order to separate the effects of different frequencies and so leakage is a confusing phenomenon.

If we define

\[
D_N(w) = x_n \sin\left(\frac{\pi n}{2} w\right) \sin\left(\frac{\pi n}{2}\right) \frac{2}{w N}
\]

then for \( N \) large and \( w \) small,

\[
D_N(w) \approx \frac{\sin\left(\frac{\pi n}{2} w\right)}{w N} \frac{2}{N}
\]

(3.32)

So the amplitude of the Fourier transform of \( x_0, \ldots, x_{N-1} \) where \( x_n = \cos(wt + \phi) \) is a function of (3.32), centred at \( w \) and rescaled so that the zeroes are separated by \( \frac{2\pi}{N} \) (the distance between adjacent Fourier frequencies).
Now if $w$ is itself a Fourier frequency, say $w_k$, then $J_j$ is zero when $j = k$ and is nonzero for $j = k$ (in fact it equals $c_1 + c_2 = \cos \theta$).

If $w$ is not a Fourier frequency then all the $J_j$ are nonzero.

The appearance of nonzero terms in the transform is due to a sinusoid of a different frequency - this is defined to be leakage. Fourier analysis (or periodogram analysis) is carried out in order to separate the effects of different frequencies and so leakage is a confusing phenomenon.

If we define

$D_N(w) = \sin\left(\frac{\pi w}{2}\right) \left(\frac{N}{\sin\left(\frac{\pi w}{2}\right)}\right)$

then for $N$ large and $w$ small,

$D_N(w) \approx \frac{\sin\left(\frac{\pi w}{2}\right)}{\frac{\pi w}{2}}$  \hspace{1cm} (3.32)

So the amplitude of the Fourier transform of $x_0, \ldots, x_{N-1}$ (where $x_t = \cos(wt+\varphi)$) is a function of (3.32), centred at $w$ and rescaled so that the zeroes are separated by $\frac{\pi}{N}$ (the distance between adjacent Fourier frequencies).
So, when \( w \) is not a Fourier frequency, only the values of the transform that are close to \( w \) are large.

Even if \( x_t \) consists of some sum of functions (i.e. sine and cosine functions) at several frequencies, the above will still hold true. So if we plot the periodogram as defined in note (vi), or even a function thereof, large values of \( I(w) \) will indicate nonzero frequencies in the data. This will be discussed more fully in section 3.6.

3.5 PROPERTIES OF \( a \) AND \( b \)

In the previous section, estimates of \( a \) and \( b \) in the model

\[
X_t = \sum_{i=0}^{k} (a_i \cos(w \cdot t) + b_i \sin(w \cdot t)) - \epsilon_t
\]  

were found.

In this section, it will be verified that the estimates given by (3.24) - (3.27) are unbiased, by using a different procedure. This verification is not necessary, but the technique involved facilitates computation of the properties of the estimates.

(3.33) above may be regarded as a standard multiple regression model. So define

\[
X = Z + \epsilon
\]

where
\[ Y = (x_0, x_1, \ldots, x_{N-1}) \] (dimension N)
\[ \mathbf{Z} = (z_0, z_1, \ldots, z_{N-1}) \] (\')
\[ \mathbf{Z} = (a_0, a_1, b_1, \ldots, a_k, b_k) \] (dimension 2k+1)

and
\[
\begin{pmatrix}
1 & \cos(0w) & \sin(0w) & \ldots & \sin(N-1)w \\
1 & \cos(1w) & \\
1 & \cos((N-1)w) & \sin((N-1)w) & \ddots & \sin((N-1)w) \\
1 & \cos((N-1)w) & \sin((N-1)w) & \ddots & \ddots & \ddots
\end{pmatrix}
\]

where, without loss of generality, we assume N is odd.

Then, by definition of the linear regression model,
\[ \beta = (Z'Z)^{-1}Z'Y \] (see for example, Draper and Smith (1966))

since \( Z \) is of full rank and \( \mathbf{X} \) is a white noise process.

hence
\[ a_o = \sqrt{N} \]
\[ a_k = \frac{2}{N} N \cos(\frac{1}{2}w) \]
\[ b_k = \frac{2}{N} N \sin(\frac{1}{2}w) \]

and if N is even
\[ a_k = \frac{2}{N} N \cos(\frac{1}{2}w) \] as before.

If we assume the \( z_i \) 's come from a purely random process
i.e., \( E(z_i) = 0 \) \( \forall i \)
\( \text{Var}(z_i) = 0 \) \( \forall i \)
\[ \text{Cov}(z_i, z_j) = 0 \forall i, j \] (3.34)

then it follows that
\[ E(a_i) = a_i \] \( \forall i \)
\[ E(b_i) = b_i \] \( \forall i \) (3.35)
and \[ V(a_i) = \frac{2}{N} \left[ \frac{N}{2} - \cos^2(w_i t) \right] \]
\[ = \frac{2\sigma^2}{N} \quad i = 0 \quad \text{and} \quad i = \frac{N}{2} \]
\[ \frac{2\sigma^2}{N} \quad i = 0 \quad \text{or} \quad i = \frac{N}{2} \]

Also \[ \text{Cov}(\hat{a}_i, b_j) = 0 \quad \forall i, j \]

The variances of estimates are obtained simply by noting that the covariance matrix of \( \hat{a} \) is given by \( (Z'Z)^{-1} \frac{\sigma^2}{N} \) (by definition). But \( Z'Z \) is a diagonal matrix due to the orthogonality relations given below:

(a) \[ \cos(w_i t) \cos(w_k t) = \begin{cases} \frac{N}{2} & k = j \\ 0 & k \neq j \end{cases} \]

(b) \[ \sin(w_i t) \sin(w_k t) = \begin{cases} \frac{N}{2} & k = j \\ 0 & k \neq j \end{cases} \]

(c) \[ \cos(w_i t) \sin(w_k t) = 0 \quad \forall j, k \]

(d) \[ \cos(w_i t) = 0 \quad \forall j \]

(e) \[ \sin(w_i t) = 0 \quad \forall j \quad \text{(3.36a)} \]

3.6 PERIODOGRAM ANALYSIS

If we decide to model our observed time-series \( x_0, x_1, \ldots, x_{N-1} \) by

\[ x_t = \sum_{i=0}^{k} \left( a_i \cos(w_i t) + b_i \sin(w_i t) \right) + \epsilon_t \quad (3.37) \]
(a purely random process) \( v_t \), some \( k \), then in general, the \( k, w_1, w_2, \ldots, w_n \) are unknown.

We define

\[
\omega_j = 2^{-j/N}; \quad j = 0, 1, \ldots, \left\lfloor \frac{N}{2} \right\rfloor
\]

but this may lead to the inclusion in the model of 'insignificant' terms i.e. terms where the contribution of 'functions' associated with frequency \( \omega_j \) is not significantly different from zero (\( \omega \) to the exclusion of significant terms).

In other words

\[
a_j \cos(\omega_j t) - b_j \sin(\omega_j t) = 0.
\]

Thus we wish to model

\[
x_t = \sum_{j=0}^{\left\lfloor \frac{N}{2} \right\rfloor} \left( a_j \cos(\omega_j t) - b_j \sin(\omega_j t) \right) \quad \forall t
\]

and then only actually include those terms in the model which are different (significantly) from zero.

It turns out that the way around this problem is reasonably easy. Model by equation (3.38) and find estimates of \( a_j \) and \( b_j \) by using the \( a_j \) and \( b_j \) as defined by (3.24)-(3.29).

If \( \omega_j \) is a true model frequency, then \( a_j \) and \( b_j \) should be close to \( a_j \) and \( b_j \), and so the squared amplitude (i.e. \( a_j^2 + b_j^2 \)), or any linear function thereof, will be nonzero. If \( \omega_j \) is not a model frequency, then this effectively estimates the coefficients of a term that should not be in the model, so
Thus, for \( w, w_1, \ldots \), a plot of \( (a_j^2 + b_j^2) \) (or any linear function thereof) against \( j \), will be such that if \( w \) is near a true \( w_j^* \) of the model, then its squared amplitude will be nonzero. See also notes (vi) and (viii) in section 3.4.1.

Define the (sample) periodogram of our time-series \( x_0, x_1, \ldots \),

\[
I(w) = \sum_{n=1}^{N-1} \left( X_n \cos(\omega n) + iX_n \sin(\omega n) \right)^2
\]

where

\[
a(w) = \sum_{n=1}^{N} X_n \cos(\omega n) = \sqrt{2} a_w
\]

\[
b(w) = \sum_{n=1}^{N} X_n \sin(\omega n) = \sqrt{2} b_w
\]

(where \( a_w \) and \( b_w \) are as in (3.25) and (3.39)). (Note that this differs from the definition given in note (vi), section 3.4.1.)

Alternatively, we may write

\[
I(w) = \frac{2}{N} \left| \sum_{n=1}^{N} x_n e^{-i\omega n} \right|^2
\]

\( I(w) \) is defined for all \( w \) in \((-\pi, \pi)\), but it is only evaluated at the frequencies \( w_j \) (where \( w_j = 2^{-j} \pi \) and \( j = 0, 1, \ldots \)) since \( I(w) \) is an even function and due to the definition of \( a_j \) and \( b_j \) in the model (3.38).

If \( w \) coincides with one of the true \( w_j^* \) in the model, \( w_j^* \) say, then

\[
\sqrt{N} a_j^* = a(w_j)
\]

and

\[
\sqrt{N} b_j^* = b(w_j)
\]
Thus, if \( w_1 = w^* \)

\[
\text{E}(I(w_1)) = \frac{N}{2}E(a^2_1) - E(b^2_1)\]

But \( E(a^2_1) = E(b^2_1) = \sigma^2 \) (by (3.36)) \( i \neq 0 \) and \( i \neq \frac{N}{2} \)

so

\[
\text{E}(I(w_1)) = \frac{N}{2}(a^2_1 - b^2_1) + 2\sigma^2
\]

or

\[
\text{E}(I(w_1)) = \frac{N}{2}c^2 + 2\sigma^2 \tag{3.42}
\]

If \( w_1 = w^* \) (\( \forall \)) then

\[ R^2_{\text{L}} = 0 \]

so

\[
\text{E}(I(w_1)) = 2\sigma^2
\]

So as \( w_1 \) approaches each of the \( w^* \), the ordinate is of order \( N \) and
the periodogram has a large peak. Thus, the location of the true
frequencies are noted (approximately), whenever a peak occurs in
the periodogram.

3.7 SAMPLING PROPERTIES OF THE PERIODGRAM

The model we have used for our series of observations \( x_0, \ldots, x_{N-1} \)

\[
x_t = \sum_{i=0}^{k} (a_i \cos(w_i t) + b_i \sin(w_i t)) + \varepsilon_t
\]

where \( \varepsilon_t \) is purely random process

and this can be rewritten as

\[
x_t = \sum_{i=1}^{R} \cos(w_i t + \phi_i) + \varepsilon_t
\]
where the \( e_i \) here are the true \( e_i \) (and not necessarily \( 2^{-i/N} \)) and the \( \phi_i \) are independently and rectangularly distributed on \((-\pi, \pi)\).

Let \( \bar{R}_{ij} = 0 \) \( \forall i \), and suppose \( x_t \) is a Gaussian random process.

Thus

\[
x_t \sim N(0, \sigma^2_x) \quad \forall t \text{ independently and so}
\]

\[
x_t \sim N(0, \sigma^2_x) \quad \forall t \text{ independently (since the } \bar{R}_{ij} = 0)\]

Now \( a(w_j) \) and \( b(w_j) \), as defined by (3.39) and (3.40), are linear combinations of the \( x_t \)'s thus \( a(w_j) \) and \( b(w_j) \) are normally distributed with zero mean and variance given by

\[
V(a(w_j)) = V(b(w_j)) = \frac{\sigma^2_x}{2} \frac{\cos^2(w_j t)}{j=0 \text{ and } j = \left\lfloor \frac{N}{2} \right\rfloor}
\]

\[
= \frac{\sigma^2_x}{2} \quad \text{otherwise}
\]

So

\[
a(w_j) \sim N(0, \frac{\sigma^2_x}{2}) \quad j = 0 \text{ and } j = \left\lfloor \frac{N}{2} \right\rfloor
\]

\[
a(w_j) \sim N(0, \frac{\sigma^2_x}{2}) \quad \text{otherwise}
\]

and similarly for \( b(w_j) \)

Now by using the orthogonality relations for the functions \( \cos(w_j t) \) and \( \sin(w_j t) \)(see (3.36a)), we can show that

\[
\text{cov}(a(w_j) b(w_l)) = \frac{\sigma^2_x}{8} \delta_{j,l} \frac{\sin(w_j t)}{t} \sin(w_l t)
\]

\[
= 0 \quad \forall j, l \neq 0
\]

Even though \( e_i \) are defined as random variables, they retain constant values for each realization.
and

\[
\text{cov}\left\{ a(w_j), b(w_j) \right\} = 0 \quad \forall j \neq \ell
\]  

(3.46)

But, \(a(w_j)\) and \(b(w_j)\) are linear combinations of the \(z_k\) and hence have a multivariate normal distribution. They are uncorrelated by (3.45) and hence independent. Thus

\[
I(w_j) = a^2(w_j) + b^2(w_j) \quad \text{(by (3.39))}
\]  

(3.47)

and

\[
I(w_j) = a^2(w_j) \quad j = 0 \text{ or } j = \frac{N}{2}
\]  

(3.48)

(since \(b(w_j) = 0\) if \(j = 0\) or \(j = \frac{N}{2}\))

So

\[
E(I(w_j)) = 2 \mu_j \quad \forall j
\]  

(3.49)

and

\[
\text{var}(I(w_j)) = \begin{cases} 4 \mu_j^2 & j \neq 0, \text{ or } j = \frac{N}{2} \vspace{1cm} \\ 4 \mu_j^2 & \text{otherwise} \end{cases}
\]

(3.50)

By (3.41), we may write \(I(w_j) \) i.t.o. \( e^{-iw_j t} \)

\[
f(w_j) = 2 \mu_j e^{-iw_j t}
\]
or more generally

\[ I(w) = \frac{2}{N} \sum_{t} x_t e^{-iwt} \]

But then

\[ I(w) = \frac{2}{N} \left( \sum_{t} x_t \cos(wt) - \sum_{t} x_t \sin(wt) \right) \]

\[ \times \left( \sum_{t} x_t \cos(ws) + \sum_{t} x_t \sin(ws) \right) \]

\[ + \frac{2}{N} \sum_{t \neq s} x_t x_s \cos((t-s)w) \]

\[ = 2 \sum_{h=-(N-1)}^{N-1} \frac{1}{N} \sum_{t=0}^{N-h-1} x_t x_{t+h} \cos(hw) \]

\[ = 2 \sum_{h} c_h^2 \cos(hw) \quad (3.51) \]

(where \( c_h^2 \) is the sample acvf as in section 2.1.)

So we have succeeded in writing the periodogram i.t.o. the sample acvf. Thus since we can express the sdf in terms of the acvf, it seems likely that some relationship exists between the sdf and the periodogram. We shall see this relationship in the next chapter.

Now all the above results hold if all the \( R_h \) in

\[ X_t = \sum_{h} R_h \cos(hw) + \sum_{h} R_h \sin(hw) \]

are zero. Suppose not all of the \( R_h \) are zero.
Define \[ x_t = z_t + \xi_t \quad \forall t \]

where \[ z_t = z_i R_i \cos(w_i t + \phi_i) \]

The \( i \)'s are just some constants, and so \( z_t \) is independent of \( z_{i'} \) for all \( i \) and \( t \). Thus \( \{z_t \} \) and \( \{\xi_t \} \) are independent processes.

At this stage it becomes necessary to quote a result not previously given. It will be given in the form of a lemma, the proof of which follows by definition of the acvf.

**Lemma 2**

If \( x_t = z_t + \nu_t \) where \( z_t \) and \( \nu_t \) are independent processes, then

\[ \gamma_x(h) = \gamma_z(h) + \gamma_\nu(h) \]

where \( \gamma_x(h) \) is the acvf of the process \( \{x_t\} \).

Using this lemma, we may write

\[ \gamma_x(h) = \gamma_z(h) - \gamma_\nu(h) \]

But

\[ \gamma_z(h) = \frac{1}{2} \sum_{i=1}^{N-1} R_i^2 \cos(\phi_i h) \]

and

\[ \gamma_\nu(h) = R \]

where

\[ h = 0 \]

Now

\[ I(w) = \frac{(N-1)}{2} \cos(hw) \quad \text{by (3.51)} \]

\[ h = -(N-1) \]

\[ z_t = z_i R_i \cos(w_i t + \phi_i) : \text{the } \{i\} \text{ are independent rectangular r.v.'s} \]
ard so

\[ E(I(w)) = \frac{2}{\pi} E(c_n) \cos(hw) \]

\[ = 2 \sum (1 - \frac{h}{N}) \chi(h) \cos(hw) \quad (by \quad (2.29)) \]

but \( \chi(h) = \chi(h) - \gamma(h) \)

and substituting gives

\[ E(I(w)) = \sum R_{\lambda}(h)(1 - \frac{h}{N}) \cos(hw) \cos(hw) + 2c \]

(3.52)

We now only need simplify the term inside the braces \{ \} in (3.52).

It turns out (3.52) can be written as

\[ E(I(w)) = \sum R_{\lambda}(h) \cos(hw) \]

(3.53)

where

\[ g_{\lambda} = \frac{\sin^2\left(\frac{N(w-w)}{2}\right)}{\sin^2\left(\frac{w}{2}\right)} \]

and

\[ h_{\lambda} = \frac{\sin^2\left(\frac{N(w-w)}{2}\right)}{\sin^2\left(\frac{w}{2}\right)} \]

Outline proof:

We need to simplify

\[ (N-1) \]

\[ \sum (1 - \frac{h}{N}) \cos(hw) \cos(hw) \]

where \( h_{\lambda} = \frac{N(w-w)}{2} \)

Now

\[ \sum (N-1) \chi(h) \cos(hw) \]

and

\[ \sum \frac{\sin(u - \frac{\pi}{2})}{\sin(u)} \]

\[ \sum \frac{\cos(s)}{\sin(s)} \]
Also
\[ \frac{\sum_{u=0}^{N-1} \sin((u+\frac{1}{2})\omega)}{\sin^2(\frac{\omega}{2})} = \frac{\sin^2(\frac{N\omega}{2})}{\sin^2(\frac{\omega}{2})} \]
and
\[ \cos^2 \omega = \frac{1}{2} \left( \cos(\omega + \frac{\pi}{2}) + \cos(\omega - \frac{\pi}{2}) \right) \]

Combining the above facts will provide the result (3.53).

So, as \( \omega \to \omega \), the term \( (g_\omega h_\omega) \) in (3.53) gives a peak of size \( N \).

Thus, if \( x \) has a sine cosine function of frequency \( \omega \), and if \( \omega \) is of the form \( 2\pi j/N \) (some \( j \)), then \( I(\omega_j) \) will have a peak of height \( N^2 \rho^2 \) at \( j \).

Having derived \( E(I(\omega)) \), all that is now required to complete this section is (a) \( \text{Cov}(I(\omega_j), I(\omega_k)) \)
and (b) \( \text{Var}(I(\omega_j)) \).

These results will be stated here and the proofs given in appendix A4. (Assume \( R = 0 \) \( \forall t \))

(a) \( \text{Cov}(I(\omega_j), I(\omega_k)) \)
\[
= \frac{4K_4}{N} \cdot \frac{\cos^2(\omega_j - \omega_k)}{N} \cdot \left( \frac{\cos(\omega_j - \omega_k)}{N} - \frac{\cos(\omega_j + \omega_k)}{N} \right)
\]
\( j \neq 0, k \neq 0 \)

(where \( \rho_h = \cos(h_\omega \omega) \))
\( \rho_{\omega h} = \cos(h_\omega \omega) \)
\( K_4 = E(x_\omega^4) = 3 \sigma^4 \chi \)

and we have assumed the \( x_\omega \) are independent \( \forall t \).)

\[
\text{Cov}(I(\omega_j), I(\omega_k)) = \frac{4K_4}{N} \cdot \frac{\cos^2(\omega_j - \omega_k)}{N} \cdot \left( \frac{\cos(\omega_j - \omega_k)}{N} - \frac{\cos(\omega_j + \omega_k)}{N} \right)
\]
(3.54)
Setting \( w_1 = w_0 = w \) and assuming \( w \) of the form \( 2r/N \) (some integer \( r \)) then

\[
(b) \quad V(I(w)) = \begin{cases} \frac{4K}{N} & w = 0 \\
\frac{4K}{N} + \frac{1}{N^2} + O\left(\frac{1}{N^2}\right) & \text{otherwise}
\end{cases}
\]

(3.55)

3.8 SUMMARY AND DISCUSSION

Since all functions (periodic or nonperiodic) can be written in the form

\[
g(t) = \sum_{k=0}^{\infty} \left( a_k \cos(w_k t) + b_k \sin(w_k t) \right)
\]

(by the theory of chapters one and two), in this chapter we have seen that, having decided on the following model

\[
x_t = \sum_{i=0}^{N-1} \left( a_i \cos(w_i t) + b_i \sin(w_i t) \right) + \epsilon_t \quad \text{for} \quad t \in \mathbb{Z}
\]

it is possible to estimate \( a_i, b_i \) and \( w_i \). This can be done by modelling our observed time series \( x_0, \ldots, x_{N-1} \) by

\[
x_t = \sum_{i=0}^{N-1} \left( a_i \cos(w_i t) + b_i \sin(w_i t) \right) + \epsilon_t \quad \text{for} \quad t \in \mathbb{Z}
\]

where \( w_i = 2r/N \).
Estimates $a_i$ and $b_i$ were obtained and these turned out to be

$$a_i = \frac{2}{N} \sum_{t=0}^{N-1} x_t \cos(w t) \quad i = 0, \ldots, \frac{N}{2}$$

$$b_i = \frac{2}{N} \sum_{t=0}^{N-1} x_t \sin(w t) \quad i = 1, 2, \ldots, \frac{N}{2}$$

A function called the periodogram, $I(w)$, is formed where

$$I(w_j) = a^2(w_j) + b^2(w_j)$$

and

$$a(w_j) = \frac{2}{N} \sum_{t=0}^{N-1} x_t \cos(w t) = \sqrt{\frac{N}{2}} a_j$$

$$b(w_j) = \frac{2}{N} \sum_{t=0}^{N-1} x_t \sin(w t) = \sqrt{\frac{N}{2}} b_j$$

and then $I(w_j)$ is plotted against $j$.

If one of the 'true' \(\omega\)'s takes the form

$$\omega_j = 2^{-j}, N = w_j \quad \text{(say)}$$

then $I(w)$ exhibits a (distinct) peak at $j$. Thus we can estimate the $\omega_j$, $a_j$ and $b_j$.

However, we may incorporate irrelevant frequencies into the model, so what we really need is a test for periodogram ordinates to determine which values are significantly different from zero (see appendix A5) and hence our final model is

$$x_t = \sum_{i=0}^{\frac{N}{2}} a_i \cos(w_i t) + b_i \sin(w_i t) \quad t = 0, \ldots, N-1$$

where some of the $a_i$'s and $b_i$'s may be (approximately) zero.

The sampling properties of $I(w)$ were derived and a link was also established showing a relationship between $I(w)$ and the sample acvf (and hence possibly with the sdf). It turns out that $I(w)$ is
distributed as $h(w)\chi^2_2$ (this will be shown in the next chapter)
where $h(w)$ is the sdf of $X$. Also, $V(I(w)) = h^2(w)$ (also shown in the next chapter) thus the variance of the periodogram estimate does not decrease as our sample size increases. Since estimates of frequencies near one another have independent distributions, the plot of $I(w)$ against $j$ (or $w$) will be unstable (this fact is also seen from the $V(I(w))$ given by (3.55)).

For example, if the periodogram of a white noise process (i.e., a purely random process) were to be computed, since the sdf of this process is a straight line (since $h(w) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{1w} \gamma(T) dT$ but $\gamma(T)$ is constant (zero) $V > 0$) we would expect the periodogram peaks to 'die out' as the sample size increased - this is not the case. The periodogram remains as wild for large samples as for smaller ones (and in fact has coefficient of variation = 100%).

Since the peaks are randomly placed, by taking an average of all possible white noise periodograms (for varying sample sizes) at each frequency a straight line (approximately) should be obtained. This gives some indication of the relationship between the sdf and the periodogram.

Thus a way of reducing (or eliminating) the variance of the periodogram ordinates, is to average neighbouring values (since if independent estimates are averaged, the variance of the average is less than the variance of each of the values in the average). This 'averaging' is called spectral analysis, which is discussed in the next chapter.
We have seen that the periodogram effectively determines whether a frequency $w_j$ (or rather components associated with $w_j$) is 'necessary' in our model.

$$x_t = \sum_{j=0}^{N} (a_j \cos(w_j t) + b_j \sin(w_j t)) + \epsilon_t \quad \forall t.$$  

A simple technique devised by Buys-Ballot (1847) is given in appendix A6. This technique allows us to determine whether the observed time-series has period $T$, for any given integer $T$. 
CHAPTER 4: THE SPECTRUM

In chapters one and two it was shown that if \( X_t \) is a stationary process with spectral density function (sdf) \( h(w) \) and autocovariance function (acvf) \( \rho(t) \) \( (t \) an integer), then

\[
h(w) = \sum_{t=-\infty}^{\infty} \rho(t) \cos(tw)
\]  

(4.1)

if \( X_t \) is real-valued (see section 2.3 and specifically (2.22) which relates the nsdf (normalized sdf) to the acrf (autocorrelation function). An obvious estimate of \( h(w) \) would be

\[
h(w) \approx \frac{1}{2\pi} \sum_{t} \rho(t) \cos(tw)
\]

(4.2)

(where \( \rho(t) \) is the (sample) acvf based on our realization of \( X_t \); and is defined in section 2.4).

In chapter three, where we dealt with the (sample) periodogram \( I(w) \), it was shown that

\[
I(w) = 2 \sum_{h=-(N-1)}^{(N-1)} \rho(h) \cos(hw)
\]

(4.3)

where \( I(w) \) is based on a realization \( x_0, x_1, ..., x_{N-1} \) (see section 7 and specifically (3.51)).

Thus, when we compare (4.2) with (4.3), it is obvious that a relationship exists between \( I(w) \) and \( h(w) \) (an estimate of the sdf). This relationship was fleetingly touched upon in the
summary of the last chapter (section 3.8), and will be dealt with more formally here. Once we have established this relationship, the uses and interpretations of the sdf will follow from those of the periodogram, thus making clear the reason for defining this function. More 'efficient' estimates of the sdf will also be considered in this chapter.

4.1 THE PERIODOGRAM AS AN ESTIMATE OF THE SPECTRUM

Suppose, w.l.o.g., that for our real-valued (discrete) process \( \{X_t\}, \) \( E(X_t) = 0 \) and \( h(w) \) is continuous \( \forall w. \)

Now \( \psi(t) \) can be estimated by \( c_i^* \) \( (t = 0, 1, \ldots, N-1) \) if we have a realisation \( x_0, x_1, \ldots, x_{N-1} \), thus the obvious estimate of (4.2) is

\[
\hat{\psi}(w) = \frac{1}{2} \sum_{t=-(N-1)}^{N-1} c_i^* \cos(tw) \tag{4.4}
\]

Consider \( I(w) \) as in (3.39) and define

\[
I^*(w) = \frac{1}{4\pi} I(w) \tag{4.5}
\]

\[
= \frac{1}{2\pi} \sum_{t=-(N-1)}^{N-1} c_i^* \cos(tw) \tag{4.6}
\]

\[= h(w) \text{ (defined in (4.1))} \]

Hence

\[
E(I^*(w)) = \frac{1}{2\pi} \int \frac{1}{N} E(c_i^*) \cos(tw) \text{ d}w \tag{2.29}
\]

(since \( E(I(w)) = \frac{1}{2\pi} \int E(c_i^*) \cos(tw) \text{ d}w \)).
Thus $I^*(w)$ is an asymptotically unbiased estimate of $h(w)$. Now in section 3.7, we saw that

$$V(I(w)) \rightarrow 0 \text{ as } N \rightarrow \infty \quad \text{(by (3.55))}$$

hence

$$V(I^*(w)) \rightarrow 0 \text{ as } N \rightarrow \infty$$

thus $I^*(w)$ is an inconsistent estimate of $h(w)$ (also see appendix A7, result 9). What we really desire is a consistent estimate of $h(w)$ (and hence $f(w)$).

Now $V(I^*(w))$ does not tend to zero since it contains 'too many' acv's (autocovariances) - this is since $I^*(w)$ involves $N$ acv's and although the variance of each acv is of order $\frac{1}{N}$ (see section 2.4), the cumulative effect of $N$ of these acv's produces a variance of order 1.

4.2 CONSISTENT ESTIMATES OF THE SDF

By the above argument, it seems reasonable to omit some of the acv's in (4.6). This will reduce the variance, but will influence the expected value also.

If $h(w)$ is continuous (i.e. $X_t$ has a continuous spectrum) then

$$r(t) \rightarrow 0 \text{ as } \left| t \right| \rightarrow \infty$$

(by the implications of the Wiener-Khintchine theorem)

and so if only the acv's in the tail of the (sample) acvf. are omitted, then (hopefully), the bias will not be too serious.

Hence a 'reasonable' estimate of $h(w)$ would seem to be

$$\hat{h}(w) = \frac{1}{2\pi} \sum_{t=-M}^{M} c_t \cos(wt) \quad (4.8)$$
where $M = N-1$ is some fixed truncation point yet to be specified. Equation (4.8) can be considered as a truncated periodogram.

Note that

$$E(\hat{h}(w)) = h(w) \text{ as } M \to \infty$$

thus if $M$ is some function of $N$ such that as $N \to \infty$, $M \to \infty$, then

$$\hat{h}(w)$$

is an asymptotically unbiased estimate of $h(w)$.

Heuristically, since $h(w)$ contains only $2M+1$ acv and $I^*(w)$ contains $2N$ acv (or more correctly, since $c^*_t = c^*_t$, $M = 1$ acv as compared with $N$ acv), it might be reasonable to suppose

$$V(h(w)) \approx \frac{M}{N} V(I^*(w))$$

which is of order $\frac{M}{N}$.

So if $M = \infty$ as $N \to \infty$ and $\frac{M}{N} \to 0$ as $N \to \infty$, then the bias and variance of $\hat{h}(w)$ should tend to zero and thus $\hat{h}(w)$ will be a consistent estimate of $h(w)$.

The obvious extension of (4.8) would seem to be

$$h(w) = \frac{1}{2} \sum_{t=-N+1}^{N-1} c^*_t \cos(tw) w < w <$$

To obtain (4.8) from (4.9), define

$$c^*_t = \begin{cases} 1 & \text{if } t < M \\ 0 & \text{otherwise} \end{cases}$$

We can say (4.9) is just a weighted average of acv or periodogram ordinates. When we recall the summary of the last chapter (i.e. section 3.3), this agrees with the ideas proposed there.

Since $c^*_t$ (and hence $c^*_t$) and $\cos(tw)$ are even functions, one of the restrictions we may wish to impose is that $c^*_t$ also be an
even function. If this is the case, then it is possible to rewrite (4.9) as

\[ h(w) = \frac{1}{2\pi} \int_{\mathbb{Z}} \sum_{t \in \mathbb{N}} c_t e^{-itw} \]  

(4.10)

So

\[ I^*(w) = \frac{1}{2\pi} \int_{\mathbb{Z}} \sum_{t \in \mathbb{N}} c_t e^{-itw} \quad -\pi < w < \pi \]  

(4.11)

where

\[ \sum_{t \in \mathbb{Z}} = 1 \quad \forall w \]

Inverting equation (4.11) gives

\[ c_t = \int_{\mathbb{Z}} I^*(w)e^{itw} \quad |t| < N \]

(i.e multiply both sides of (4.11) by \( e^{itw} \), some \( t \), and integrate over \( w \))

so

\[ \hat{h}(w) = \frac{1}{2\pi} \int_{\mathbb{Z}} I^*(\omega)e^{i\omega d\theta} \cdot e^{-itw} \]

\[ \hat{h}(w) = \int_{\mathbb{Z}} I^*(\omega) \left( \frac{1}{2\pi} \int_{\mathbb{Z}} e^{-it(w-d\theta)} \right) d\theta \]

\[ = \int_{\mathbb{Z}} I^*(\omega) W_N(w-d\theta) \quad \text{say} \]  

(4.12)

(\text{where } W_N(w-d\theta) = \frac{1}{2\pi} \int_{\mathbb{Z}} e^{-it(w-d\theta)})

i.e. \( \hat{h}(w) \) can not only be expressed as a weighted sum of \( acv^8 \), but also as a weighted integral of the (modified) periodogram, \( I^*(\omega) \). The weighting function, \( W_N(w-d\theta) \), turns out to be the discrete Fourier transform of \( W_N \). It is possible to consider (4.12) as a 'smoothing of the periodogram' process (again supporting the ideas presented in section 3.8).
Note that since
\[
\hat{h}(w) = \frac{1}{2\pi} \int_{-\infty}^{\infty} h(t) e^{-iwt} dt
\]
and
\[
\hat{w}_N(w) = \frac{1}{2\pi} \int_{-\infty}^{\infty} w(t) e^{-iwt} dt
\]
then inverting (4.13) gives
\[
I = \int_{-\infty}^{\infty} w(t) \hat{w}_N(w) e^{iwt} dt
\]
(4.14)

If \( \hat{w}(t) \) is a (real) even function of \( t \), then so is \( \hat{w}_N(w) \) and hence
\[
\hat{w}_N(w) = \frac{1}{2\pi} \int_{-\infty}^{\infty} w(t) \cos(\tau t) dt
\]
(4.15)

is called the lag window and \( \hat{w}_N(w) \) the spectral window.

4.3 SPECTRAL WINDOWS

The reason for the name 'spectral window' makes intuitive sense—we think of \( \hat{w}_N(w) \) as being zero outside some (small) interval, \((-\delta, \delta)\) say, and so (4.12) can be regarded as enabling us to look at \( I^w(w) \) through a small 'window' from \((w-\delta)\) to \((w+\delta)\).

Obviously, the form of \( \hat{w}_N(w) \) (or equivalently \( I^w(w) \)) may vary, since we are considering \( h(t) \) as either a weighted sum or weighted integral of the (modified) periodogram ordinates of \( I^w(w) \). Thus the 'weight' we attach to each acv is of some importance. Certain weighting function, will have better properties than others.

Several authors have evolved their own windows and presented claims as to why their spectral windows are 'suitable'. The pros and cons of the windows will not be discussed in any detail in
his work, but rather just their general forms will be given. As \( w_t \) is just a weighting function, the 'form' of some of the lag-windows will make intuitive sense.

4.1 Selected Windows

1. The general periodogram

\[
\hat{\gamma}_N = 1 \quad \forall t
\]

hence

\[
\hat{\gamma}_N(\omega) = \frac{1}{2\pi} \sum_{|t| < N} \cos(\omega t) \quad \text{(by definition)}
\]

\[
= \frac{1}{2\pi} \left( \frac{\sin(N - \frac{1}{2})u}{\sin(\frac{1}{2})} \right)
\]

(since \( \sum_{t=0}^{N-1} e^{it} = (e^{iN} - 1)/(e^i - 1) \))

hence

\[
\cos(\omega t) = \cos \left( \frac{(N-1)\omega}{2} \right) \frac{\sin(N\omega/2)}{\sin(\omega/2)}
\]

and

\[
\cos(\omega t) = 2 \cos(\omega t/2) - 1
\]

Fig 4.1

2. The truncated periodogram

\[
\gamma_N = \begin{cases} 1 & |t| < M \\ 0 & \text{otherwise} \end{cases}
\]

\( \gamma_N \) is only defined for integer \( t \), however in the graphs, \( \gamma_N \) is 'defined' (mapped) for all \( t \).
hence
\[
W_N(t) = \frac{1}{2} \left( \frac{\sin(M \cdot \frac{1}{2})}{\sin(\frac{1}{2})} \right).
\] (4.17a)

(proven by using the same procedure as for the general periodogram)

Fig. 4.2

3. Bartlett’s window (a) (Bartlett (1950))

\[
y(t) = \begin{cases} 
1 - \frac{|t|}{M} & |t| < M \\
0 & \text{otherwise}
\end{cases}
\] (4.18)

hence
\[
y(t) = \frac{1}{2M} \left( \frac{\sin\left(\frac{\pi t}{M}\right)}{\sin(\frac{1}{2})} \right)^2
\] (4.18a)

since \( W_N(t) = \frac{1}{2} \int_{-M}^{M} (1 - \frac{|t|}{M}) \cos(\theta t) \) and this has been found already - see 'outline proof' after

Fig. 4.3

4. Bartlett’s window (b) (Bartlett (1950))

\[
y(t) = \frac{1}{2} \left( 1 - \frac{|t|}{M} \right)(1 + \frac{|t|}{M}) \quad |t| < M
\] otherwise
\[
y(t) = 0
\] otherwise
\] (4.19)
(for \( \hat{h}(w) \), see Bartlett (1950); it is not given here since Bartlett's (2) window is the more renowned)

This window enables one to work with \( c_y \) as an estimate of \( \gamma(t) \) (instead of \( c'_y \)) when estimating \( h(w) \), the estimate of the sdf. Bartlett originally divided the \( N \) observations into \( N/M \) subsamples, with each subsection containing \( M \) observations. He then computed, for each \( w \), the average of the corresponding periodogram ordinates for each section.

5. Daniell's window (Daniell (1946))

\[
\hat{h}(w) = \frac{\sin\left(\frac{\pi t}{M}\right)}{\pi t} \quad t = 0, 1, \ldots, N \tag{4.20}
\]

\[
\hat{h}(w) = \frac{1}{2M} \quad -\frac{M}{2} < \varphi < \frac{M}{2} \quad \text{otherwise} \tag{4.20a}
\]

(Daniell (1946), defined (4.20a) first and then worked backwards to obtain Fig. 4.1.1)

\( h(w) \) is estimated by averaging the periodogram over a small interval centred at \( w \) (from \( w - \frac{M}{2} \) to \( w + \frac{M}{2} \), say) i.e.

\[
h(w) = \frac{M}{2} \int_{w - \frac{M}{2}}^{w + \frac{M}{2}} \hat{\gamma}(\varphi) \, d\varphi
\]

hence the form of \( \hat{h}(w) \). For this window, \( M \) is not really a truncation point but instead determines the degree of smoothing.
applied to $I^*(\theta)$. Small $M$ implies greater smoothing.

6. The Blackman-Tukey window (Blackman and Tukey (1959))

$$
\lambda_t = \begin{cases} 
1 - 2a + 2a \cos\left(\frac{\pi}{M} t\right) & |t| < M \\
0 & \text{otherwise}
\end{cases} \quad (4.21)
$$

hence

$$
W_N(\theta) = \frac{1}{2\pi} \sum \left\{ (1 - 2a) + 2ae^{j\pi M} - 2ae^{j\pi M} \right\} e^{-j\theta t} = aD(\theta - \frac{\pi}{2M}) + (1 - 2a)D(\theta) + aD(\theta + \frac{\pi}{2M}) \quad (4.21a)
$$

(i.e. a weighted average of the truncated windows - (4.17) - over

$$
\theta - \frac{\pi}{2M} \text{ and } \theta = \frac{\pi}{2M}
$$

where

$$
D(\psi) = \frac{1}{2\pi} \frac{\sin((M-\frac{1}{2})\psi)}{\sin(\frac{1}{2})} \quad (\text{Dirichlet's kernel for (4.17a)})
$$

The next two windows are just special cases of (4.21) (and hence (4.21a)) and so no graph of $\lambda_t$ will be given.

6a) The Tukey-Hamming window (Tukey (1949))

In (4.21), set $a = 0.23$

thus

$$
\lambda_t = \begin{cases} 
0.54 + 0.16 \cos\left(\frac{\pi}{M} t\right) & |t| < M \\
0 & \text{otherwise}
\end{cases} \quad (4.22)
$$
(6b) The Tukey-Hanning window \cite{Guttman1981)}

In (4.21), set \( a = 0.25 \)

thus

\[
\begin{align*}
\alpha &= \frac{1}{2} \cos\left(-\frac{t}{M}\right) \\
&= 0, \quad \text{otherwise}
\end{align*}
\]

(4.23)

7. Parzen's window (a) \cite{Parzen1957}

\[
\alpha = \begin{cases} 
1 - \left(\frac{t}{M}\right)^2 & \text{if } |t| < M \\
0 & \text{otherwise}
\end{cases}
\]

(4.24)

\[
\text{hence}
\]

\[
W_N(f) = \frac{1}{2\pi} \left( \frac{\sin(Mf)\cos(Mf) + \cos(Mf)}{2M\sin^2(f/M) + M^2\sin^2(f/2)} \right)
\]

(4.24a)

[Also see Jenkins (1961)]

\[
\text{plotted against } t \text{ has much the same form as figure 4.5.}
\]

8. Parzen's window (b) \cite{Parzen1961}

\[
\alpha = \begin{cases} 
1 - \left(\frac{t}{M}\right)^2 & \text{if } |t| < \frac{M}{2} \\
2(1 - \frac{t}{M})^3 & \frac{M}{2} \leq |t| \leq M \\
0 & \text{otherwise}
\end{cases}
\]

(4.25)

\[
\text{hence}
\]

\[
W_N(f) = \frac{3}{8\cdot M^3} \left( \frac{\sin\left(\frac{M}{2}\right)}{1 + \frac{1}{3}\ln^2\left(\frac{M}{2}\right)} \right)
\]

(4.25a)

(see Parzen (1961))

Figure 4.6 shows two functions - the Tukey-Hanning and the Parzen (b) windows. This enables us to make comparisons between the two windows.
9. The Bartlett–Priestley window (Priestley (1962))

\[ w(t) = \begin{cases} \frac{3M^2}{4\pi^2} \left( \sin\left(\frac{\pi t}{M}\right) - \cos\left(\frac{\pi t}{M}\right) \right) & |t| \leq M \\ 0 & \text{otherwise} \end{cases} \quad (4.26) \]

hence

\[ W_N(\omega) = \begin{cases} \frac{3M^2}{4\pi} \left(1 - \frac{|n|}{M}\right) & |n| \leq M \\ 0 & \text{otherwise} \end{cases} \quad (26a) \]

(see Priestley (1962))

As in the Daniell window, Priestley 'created' the quadratic spectral window \( W(\omega) \) (which is an optimal window w.r.t. the relative MSE - see Epanechnikov (1969)) and then worked backwards to derive \( W_N(\omega) \). As in the graph of the Daniell window (figure 4.4), \( W(\omega) \) does not truncate at \( M \) and \(-M\). For both these cases, it is easier to plot the spectral window \( W_N(\omega) \) (Daniell's is just linear, and Bartlett Priestley's is quadratic).

10. The Bohman window (Bohman (1961))

\[ w(t) = \begin{cases} 1 - \frac{|t|}{M} & 0 \leq |t| \leq M \\ \frac{1}{M^2} \left(1 - \frac{|t|}{M}\right) \cos\left(\frac{\pi |t|}{M}\right) - \frac{\sin\left(\frac{\pi |t|}{M}\right)}{\pi |t|} & |t| > M \end{cases} \quad (4.27) \]
hence

$$w(t) = \begin{cases} \frac{1}{2} \left( 1 - \frac{|t|}{M} \right) \cos \left( \frac{-\pi t}{M} \right) \cos \left( \frac{\pi t}{M} \right) \\ \frac{1}{2} \left( \frac{\sin \left( \frac{\pi t}{2M} \right)}{M} \right) \cos \left( \frac{\pi t}{M} \right) \end{cases}$$

which is complicated (see Neave (1972)).

11. The Tukey-Parzen window (Parzen (1958))

\[ w(t) = \begin{cases} \frac{1 - 2a + 2a \cos \left( \frac{\pi t}{M} \right)}{M} & |t| < M \\ 0 & \text{otherwise} \end{cases} \]  

and $a = 0.282$

This is of the same form as (4.27).

Neave (1972) has compared the performances of some of these windows - namely (3), (5), (6a), (6b), (7), (8), (10) and (11).

He concluded that the Bohman and Parzen windows were superior to the others by considering the "negated derivative" of the lag windows, but that even these could be improved upon. To a lesser extent, the Tukey-Hamming window was also satisfactory.

More discussion on the choice of spectral window (or lag window) will follow in the next chapter. The sampling properties of spectral estimates are given in appendix A7, but with no details or discussion. These sampling properties are given in the form of a series of results and mainly concern the variance and covariance of spectral estimates under certain conditions.

See appendix A7 for a brief explanation.
In the next chapter, we shall see some of the problems involved in spectral estimation. Since the object of this study is to model an observed time-series 'successfully', and since it turns out that modelling is 'easier' using a periodogram approach rather than a spectral analysis approach, the properties of spectral estimates are only covered in the barest detail in Appendix A7.
CHAPTER 3: THE PROBLEMS INVOLVED IN SPECTRAL ANALYSIS

5.1 INTRODUCTION

Strictly speaking, the spectrum does not really enable us to model an observed time-series. Rather, if one calculates some spectrum estimate, we may be able to gain an idea of the model by comparing our spectrum estimate with known spectra, and also gain an idea about dominant frequencies. Alternatively, and this is the approach used in this study, we may remove all seasonal components (if any) from the model by using periodogram analysis (see chapter three).

We are then left with a set of residuals $a_0, a_1, \ldots, a_{N-1}$ say. Using techniques to be described a little later (i.e. in chapter six onwards), it may be possible to model these residuals even further by Box-Jenkins modelling and hence reduce the residual variance.

Thus we shall hopefully be in the position where we have a model consisting of seasonal components (i.e. cosine and sine functions) and some nonseasonal components. Using this model, we can now 'regenerate' the data (using the model parameters) and compare the resulting spectrum with that of the original data (or even calculate the spectrum directly from the model).

However, certain problems, which are to be discussed in this chapter, still exist. These problems emphasize the difficulty of trying to compute the spectrum of the process, from which the time-series has come, 'accurately'.

See chapter 9.4, Comment, for a discussion of this technique.
5.2 SCALE PARAMETER WINDOWS

It will be noted that for most of the spectral windows given in section 4.3.1., the truncation point, M, merely acted as a scale parameter i.e. contracted the function. For such windows, it is possible to write $\lambda_t$ in the form

$$\lambda_t = k(\frac{t}{M})$$

where $k(u)$ is a fixed continuous even function in $u$, with $k(0) = 1$. ($k(u)$ is often called a lag window generator.)

For example, window (2) was the truncated periodogram. The form of $k(u)$ is

$$k(u) = \begin{cases} 1 & |u| < 1 \\ 0 & \text{otherwise} \end{cases}$$

(since the original form of $\lambda_t$ was

$$\lambda_t = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-it\xi} \, d\xi$$

and we can now rewrite this as

$$\lambda_t = \frac{1}{2\pi} \int_{-\infty}^{\infty} k\left(\frac{\xi}{M}\right) e^{-it\xi} \, d\xi$$

(assuming $k\left(\frac{\xi}{M}\right) = 0$ \forall \xi \geq M)
k(w) only applies when M really acts like a truncation point.

Also

\[
K_N(\tilde{\omega}) = \frac{1}{2\pi} \int_{-\infty}^{\infty} k(u)e^{-i\tilde{\omega}u} \, du \tag{5.2}
\]

\[=\text{Fourier transform of } k(u)\]

hence \(K_N(\tilde{\omega})\) may be expressed i.t.o. \(\mathcal{K}_N(\tilde{\omega})\)

For \(M\) large, (5.1) may be approximated (i.e. the sum may be approximated) by (5.2) thus

\[K_N(\tilde{\omega}) = \mathcal{N} \mathcal{K}_N(M\tilde{\omega}) \tag{5.3}\]

When lag windows can be written in scale parameter form, more precise treatment of the sampling properties of spectral estimates is available. These results are given in 'result 10', appendix A7

The two main questions to be answered are

(i) which window do I use? \(\tag{5.4}\)

and

(ii) what value should \(M\) take? \(\tag{5.5}\)

3 A MEASURE OF THE PRECISION OF SPECTRAL ESTIMATES

Obviously, the single question which (5.4) and (5.5) produce is

(iii) What \(h(w)\) do I use? \(\tag{5.6}\)

A way of solving this problem is to require that \(h(w)\) has a certain precision. Parzen (1957) has suggested two techniques for assessing precision namely

\[P_1(\omega) = \frac{f(\omega)}{h(\omega)} \times \frac{h(w)}{h(w)} \tag{5.7}\]
$k(w)$ only applies when $M$ really acts like a truncation $r_{\text{int}}$.

Also

$$K_M(\theta) = \frac{1}{2\pi} \int_{-\infty}^{\infty} k(u) e^{-iu\theta} \, du$$  \hspace{1cm} (5.2)

= Fourier transform of $k(u)$

hence $W_M(\theta)$ may be expressed i.t.o., $K_M(\theta)$

For $M \geq 1$, (5.1) may be approximated (i.e. the sum may be approximated) by (5.2) thus

$$W_M(\theta) \approx MK_M(\theta)$$  \hspace{1cm} (5.3)

When lag windows can be written in scale parameter forms, more precise treatment of the sampling properties of spectral estimates is available. These results are given in 'result 10', appendix A.

The two main questions to be answered are

(i) which window do I use?  \hspace{1cm} (5.4)

and

(ii) what value should $M$ take?  \hspace{1cm} (5.5)

3 A MEASURE OF THE PRECISION OF SPECTRAL ESTIMATES

Obviously, the single question which (5.4) and (5.5) produce is

(iii) what $h(w)$ do I use?  \hspace{1cm} (5.6)

A way of solving this problem is to require that $h(w)$ has a certain precision. Parzen (1957) has suggested two techniques for assessing precision namely

$$P_1(w) = \frac{\|h(w)\|_2}{\|h(w)\|_2}$$  \hspace{1cm} (5.7)
where
\[ v^2(w) = V(h(w)) \] is the variance of \( h(w) \)

\[ b(w) = E(h(w)) - h(w) \] is bias

and

\[ z = 1 - \frac{2}{\alpha} \text{ fractile of the } \chi^2(\nu) \text{ distribution} \]

Motivation:

Asymptotically

\[
p\left( \frac{\hat{h}(w) - h(w)}{h(w)} \leq P_1(w) \right) > 1 - \alpha, \tag{5.8} \]

since

\[
p\left( \frac{h(w) - h(w)}{h(w)} \right) \geq p\left( \frac{b(w)}{h(w)} \right) \leq z - \frac{b(w)}{h(w)}, \tag{5.9} \]

But \( h(w) \) is asymptotically normal, and so the RHS of (5.9) is

set to 1 by defining

\[ z = z, \quad v(w) = v(w), \quad b(w) = b(w), \quad \text{hence result} \]

Parzen's (1957) other measure of precision is

\[
(b, \quad P_2(w) = E(h(w) - h(w))^2) \rightleftharpoons h^2(w) \tag{5.10} \\
= \left[ v^2(w) + b^2(w) \right] h^2(w) \\
= \left[ \frac{v^2(w)}{h^2(w)} + \frac{b^2(w)}{h^2(w)} \right] h^2(w) \\
\]

Since

\[
\lim_{N \to \infty} \frac{N}{N} v^2(w) = (1 - \nu) h^2(w) \int_{-\infty}^{\infty} k^2(u) du \\
\]

and \( b(w) = \int_{-\infty}^{\infty} k^2(r) h^2(r)(w) \)

(by 'result 10', appendix A7)
\[ w \in \mathbb{R}, z \pi \]

\[ k(u) = \text{scale parameter window} \]

\[ h^{(r)}(w) = \frac{1}{2\pi} \sum_{|t|<\pi} |t|^r y(t) e^{-itw} \]

\[ k(r) = \left\{ \begin{array}{ll}
1 - k(x) & x \neq 0 \\
0 & |x|^r
\end{array} \right. \]

and \( r \) is the largest integer (>0) such that \( k^{(r)} \) exists (and is finite) - see 'result 10', appendix A7

then

\[ P_1(w) = \int_{-\pi}^{\pi} k(x)dx \]

\[ \frac{1}{w} \frac{1}{h^r} \]

where \( h_r = |h(w)| h^{(r)}(w) \) (with \( r \) as before)

Also

\[ P_2(w) = \int_{-\pi}^{\pi} k^2(x)dx = \left( \frac{1}{w h^r} \right)^2 \]

Thus \( P_1(w) \) and \( P_2(w) \) are dependent on \( h(w) \) (i.t.o. \( h_r \)), on \( k^{(r)} \) and \( \int_{-\pi}^{\pi} k^2(x)dx \).

Obviously, because of this dependence, neither \( P_1(w) \) nor \( P_2(w) \) is easily calculated. To evaluate \( P_1(w) \) or \( P_2(w) \), knowledge of \( h(w) \) is required (\( h_r \)), due to the dependence on \( h_r \) - this is an unrealistic requirement.
5.4 WINDOW BANDWIDTH

In appendix A7 (specifically, result 10) it is shown that

\[ V(h(w)) = v^2(w) \cdot O\left(\frac{M}{N}\right) \]  (5.11)

and

\[ b(w) = \text{bias of } h(w) = O\left(M^{-r}\right) \]  (5.12)

Hence, as \( M \) increases, the variance increases and the bias decreases, as \( M \) decreases, the variance decreases and the bias increases. Thus no matter how we choose \( M \), \( h(w) \) is either biased or its variance is large. We require some 'happy medium'. (This problem is analogous to power and significance levels in hypothesis testing).

Suppose \( h(w) \) has two peaks \( w_1 \) and \( w_2 \) say. We want \( h(w) \) to 'reproduce' \( h(w) \) accurately, also with peaks at \( w_1 \) and \( w_2 \).

Now, by definition

\[ E(h(w)) = \int_{-\infty}^{\infty} h(w) \cdot \hat{N}_1(w) \, dw \]  (see results 1 and 2, appendix A7).

Suppose \( \hat{N}_1(w) \) is the Daniell window (given by (4.20a)), thus

\[ \hat{N}_1(w) = \begin{cases} \frac{M}{2} & \text{if } -\frac{M}{2} \leq w \leq \frac{M}{2} \\ 0 & \text{otherwise} \end{cases} \]

so

\[ E(h(w)) = \frac{M}{2} \int_{-\frac{M}{2}}^{\frac{M}{2}} h(\theta) \, d\theta \]

is average value of \( h(\theta) \) over an interval of width \( \frac{2M}{4} \) centred at \( w \).
If $M$ is so small that

$$\frac{\Delta \theta}{M} < |w_2 - w_1|$$

then the two peaks will be indistinguishable i.e. they merge into one peak. So we need $M$ large enough to be able to 'resolve' (distinguish) the two peaks i.e. we need

$$\frac{\Delta \theta}{M} < |w_2 - w_1|$$

i.e. $M > \frac{|w_2 - w_1|}{\Delta \theta}$

Also, $\hat{h}(w)$ must, as accurately as possible, reproduce the shape of $h(w)$. This implies that $h(w)$ must reproduce each peak and each trough! Thus $M$ needs to be chosen such that the width of $h(3)$ is not greater than the 'bandwidth' of the narrowest peak or trough.

Define the 'bandwidth', $B$, of a peak (or trough) at $w_0$ by the distance between $w_1$ and $w_2$ (where $w_1$ and $w_2$ are such that $h(w_1) = h(w_2) = \frac{1}{2} h(w_0)$).

Priestley (1981, p 514), has defined $B$ by

$$B = 2 \left[ \inf \frac{h''(w_0)}{h''(w_0)} \right]$$

Thus if $h(w)$ consists of several peaks and troughs, define

$$R = \left\{ \inf \frac{h''(w)/h''(w_0)}{\frac{1}{2}} \right\}$$

and

$$h''(w) = -\frac{1}{2} \left( \sum_{t=-\infty}^{\infty} t^2 \tau(t)e^{-w(t)} \right)$$

(by the definition of $h(w)$)
However we do not know \( h(w) \). If we make \( B^* \) too small (and hence \( M \) large) any 'minor' fluctuation in \( h(w) \) will be shown out of all proportion in \( h(w) \).

But

\[
\left| h''(w) \right| \leq \frac{1}{2\pi} \left( \sum t^2 |\gamma(t)| \right)
\]

(since \( \sum t^2 \gamma(t) \leq \sum t^2 |\gamma(t)| \))

thus if \( \gamma(t) \) decays quickly, \( |h''(w)| \) is small and \( B^* \) is large i.e. the rate at which \( \gamma(t) \to 0 \) is inversely proportional to \( B^* \). Thus if we can estimate this rate of decay, it is possible to estimate \( B^* \).

For windows like the truncated periodogram ((4.17a)), \( M \) represents the point beyond which \( \gamma(t) = 0 \). Thus if we can find this point, it may be possible to calculate \( B^* \). Alternatively, choose \( B^* \) large (and so \( M \) small) and progressively decrease \( B^* \) each time calculating \( h(w) \). It may be possible to detect some point at which this 'unsmoothing' has been taken too far.

Finally, it is sensible to choose \( M \) to give a compromise between the bias and variance of \( h(w) \). So we may choose \( M \) to minimize either \( P_1(w) \) or \( P_2(w) \) (defined by (5.7) and (5.10) resp.)

If we have chosen our window, \( \chi_{\text{w}}(\lambda) \), evaluate \( P_1(w) \) or \( P_2(w) \) by using asymptotic values for the bias and variance, and then minimize \( P_1(w) \) (or \( P_2(w) \)) w.r.t. \( M \) (i.e. find the derivative of either criterion w.r.t. \( M \) and set this derivative equal to zero).
5.5 CHOICE OF WINDOW

So far we have only considered the estimation of $M$, the truncation point. However the other problem of which window to choose still exists. In fact, before we can even consider estimating $M$, we need to have decided upon a window.

If we consider the truncated periodogram window (given by (4.17a)), a graph of

$$W_n(\theta) = \frac{1}{2\pi} \left\{ \frac{\sin((M + \frac{1}{2})\theta)}{\sin(\frac{\theta}{2})} \right\}$$

will indicate a main lobe at $\theta = 0$, but negative sidelobes at (approximately) $\pm \frac{3}{2M+1}$ and positive sidelobes at $\frac{5}{2M+1}$ etc.

i.e.

Thus there is considerable contribution to $E(h(w))$ from the values of $h(\theta)$ at

$$w = \frac{1}{2M-1}, \quad w = \frac{3}{2M-1} \quad \ldots \ldots$$
Now if \( \omega \) and \( \omega \) coincide with a peak in \( h(\omega) \), then this could seriously affect the value of \( E(h(\omega)) \) i.e. leakage will occur.

Often, leakage reduction is used as a criterion for window selection - e.g. if sidelobe reduction is required (i.e. sidelobe leakage reduction), then the Daniell window (4.20a) which has no sidelobes is best. (However this window has large bias i.e. it suffers from periodogram leakage due to the bias in the periodogram).

The distortion due to sidelobe leakage can be controlled by \( M \). As \( M \) increases, the window contracts and so reduces the distance between subsidiary lobes and the main lobe.

Any objective approach to selection should take into account both the bias and variance of the window estimate. This approach should then give a criterion which determines the form of window which will optimize this criterion.

In appendix A8, the approximate variance of spectral estimates is given for the set of windows described in section 4.2. If one is prepared to ignore the bias in spectral estimates, these variances may be used as a criterion for window choice.

5.6 BRIGHTENING AND TAPERING

These are techniques which try to improve the spectral estimates by transforming the data before any analysis is attempted.
6.6.1 PREWRITING

This technique takes the original process \( \{x_t\} \) and passes it through a filter to give a new process \( \{y_t\} \), i.e., a transformation of the form:

\[
y_t = \sum_u a_u x_{t-u} \quad \forall t
\]

Then

\[
h_y(w) = \left| |y_t| \right|
\]

\[
= |A(w)|^2 h_x(w)
\]

where \( A(w) = \sum_u a_u e^{-jwu} \)

Proof:

\[
h_y(w) = \frac{1}{2} \int_{-\pi}^{\pi} h_x(t) \cos(wt) dt
\]

but

\[
y(t) = E(y_t - \bar{y}) (y_t - \bar{y})
\]

where \( \bar{y} = E(y) \)

Without loss of generality, assume

\[E|x_t| = 2 \forall t\]

then

\[
y(t) = \sum_{p,q} \int_{\gamma} a_p a_q \delta(p-q) \delta(p+q)
\]

\[
= \sum_{p,q} a_p a_q \int_{\gamma} \delta(p-q) \delta(p+q)
\]

\[
= \sum_{p,q} a_p a_q \int_{\gamma} \delta(q-p) \delta(p-q)
\]

\[
= \sum_{p,q} a_p a_q \int_{\gamma} \cos(w(q-p+t)) h_x(t) dt
\]

\[
= \sum_{p,q} a_p a_q e^{jw(q-p+t)} h_x(t) dt
\]

\[
\text{Real part of }...
\]
For more on the choice of the transformation i.e. the $x_u$, see Bloomfield (1976), Chapter 6. Complex demodulation.

5.6.2 TAPERING

Here the purpose is to reduce the bias in the spectral estimates, as well as to reduce leakage.

Consider the following situation:

suppose $x_n = e^{it_0}$, $t = 0, 1, ..., N-1$

(5.15)

$J(w)$ = Fourier transform of $x_n$.

\[ J(w) \approx \frac{1}{N} \sum_{t=0}^{N-1} x_n e^{-itw} \]

\[ \approx \frac{1}{N} e^{-it(1-w)} \]

\[ \approx \frac{1}{N} e^{-i(N-1)/2} \sin \left( \frac{w}{N} \right) \]

if $1 = 0$ (see note (viii) in section 3.4.1)
Let
\[ J^*(w) = J(w) e^{i(N-1)w^2} \] (5.17)

then if \( \delta = w \)

\[ J^*(w) = e^{i(N-1)\delta/2} \frac{\sin\left(\frac{\delta}{2}\right)}{N\sin\left(\frac{\delta}{N}\right)} \]

and

\[ J^*(w - \frac{2\delta}{N}) = e^{i(N-1)\delta/2} \frac{\sin\left(\frac{\delta}{2}(w - \frac{2\delta}{N})\right)}{N\sin\left(\frac{\delta}{2}(w - \frac{2\delta}{N})\right)} \]

\[ = -e^{i(N-1)\delta/2} \frac{\sin\left(\frac{\delta}{2}(w)\right)}{N\sin\left(\frac{\delta}{2}(w)\right)} \] (if \( N \) is large)

\[ J^*(w - \frac{2\delta}{N}) = -J^*(w) \]

Similarly \( J^*(w + \frac{2\delta}{N}) = -J^*(w) \)

Define \( J_H(w) = \frac{1}{4} J^*(w - \frac{2\delta}{N}) + \frac{1}{2} J^*(w) - \frac{1}{4} J^*(w + \frac{2\delta}{N}) \) (5.17)

then

\[ J_H(0) = 0 \]

\[ J_H(w) = \frac{1}{4N} e^{i(N+1)\delta/2} \left[ \frac{2}{\sin\left(\frac{\delta}{2}\right)} \right] \]

\[ \sin\left(\frac{\delta}{2}(w)\right) - \sin\left(\frac{\delta}{2}(w + \frac{2\delta}{N})\right) \] \( \sin\left(\frac{\delta}{2}(w)\right) - \sin\left(\frac{\delta}{2}(w + \frac{2\delta}{N})\right) \)

If \( N \) is large, then

\[ \sin\left(\frac{\delta}{2}(w - \frac{2\delta}{N})\right) = \sin\left(\frac{\delta}{2}(w)\right) - \frac{2}{N} \cos\left(\frac{\delta}{2}(w)\right) \]

Operation (5.17) is known as 'hanning' (Bloomfield (1976), pg 83)

hence the notation \( J_H \)
and 
\[
\sin\left(\frac{\frac{3}{2} - w}{2} + \frac{\pi}{N}\right) = \sin\left(\frac{\frac{3}{2} - w}{2}\right) + \frac{\pi}{N} \cos\left(\frac{\frac{3}{2} - w}{2}\right)
\]
hence, after simplification 
\[
JH(w) = \frac{-\pi^2}{2N^3} e^{i(N-1)\pi/2} \sin\left(\frac{\pi}{2}(\phi - w)\right)
\]
\[
\left(\cos\left(\frac{-w}{2}\right)\right)^2
\]
\[
\left(\sin\left(\frac{\pi w}{2}\right)\right)^3
\]
(5.18)
The leakage in \(JH(w)\), given approximately by (5.18) is better
behaved than that in \(J^*(w)\) (given by (5.15)) (it contains a factor \(1/N^3\) rather than \(1/N\) and so it is smaller \(1/N\); also, \((\sin(\frac{\pi w}{2}))^3\) decays as \(1/|w|\) instead of \(1/|\phi - w|\) as in \(J^*(w)\) - thus the leakage is contained closely around \(w = \phi\).

So, if we use (5.17) and (5.16) for any series \(X_t\), then
\[
JH(w) = \frac{1}{4} J^*(w_1) + \frac{1}{4} J^*(w_2) + \frac{1}{2} J^*(w)
\]
\[
w_1 = w - \frac{2\pi}{N}
\]
\[
w_2 = w - \frac{2\pi}{N}
\]
Now \(J^*(\phi) = J(\phi)e^{i(N-1)\phi/2}\)
where
\[
J(\phi) = \frac{1}{N} e^{-19t}
\]
thus (5.19) becomes
\[
JH(w) = \frac{1}{N} e^{i\omega(N-1)/2} \sum_{t=1}^{N} e^{-i(N-1)\phi/N} e^{-it(w - 2\pi/N)}
\]
}\[
+ \frac{1}{4} e^{i(N-1)\phi/N} e^{-it\phi} e^{-i\pi t} - \frac{1}{4} e^{-i\pi t} - 1
\]
\[
\begin{align*}
&= \frac{1}{N} e^{i\pi(N-1)/2} \left[ e^{-ix} - 1 \right] + \frac{1}{4} e^{-i\pi(N-1)/2} \left[ e^{-ix} - 1 \right] \\
&= \frac{1}{4} e^{-i\pi(N-1)/2} - \frac{N-1}{N} + \frac{1}{2}
\end{align*}
\]

But
\[
\begin{align*}
e^{-i(a-b)} &= e^{-i(b-a)} = \cos(a-b) - i\sin(a-b) \\
&= \cos(b-a) - i\sin(b-a)
\end{align*}
\]
\[
= 2(\cos(b)\cos(b) - \sin(b)\sin(b))
\]
\[
= 2(\cos(b))
\]

Let \( a = \frac{N-1}{2} \) and \( b = \frac{2\pi}{N} \).

\[
\begin{align*}
a + b &= \frac{N-1}{2} + \frac{2\pi}{N} \\
&= \frac{2\pi}{N} \left( \frac{N-1}{2} + \frac{1}{2} \right) = \pi \text{ way}
\end{align*}
\]

\[
\begin{align*}
\mathcal{F}(v) &= \frac{1}{N} e^{-i\pi(N-1)/2} \left[ e^{-ix} - 1 \right] + \frac{1}{2} \cos(v)
\end{align*}
\]
\[
= \frac{1}{N} e^{-i\pi(N-1)/2} e^{ix} - \frac{1}{2} - \frac{1}{2} \cos(v) \tag{3.20}
\]

where \( d = \frac{2\pi}{N} - 1 \).

Then
\[
\begin{align*}
\mathcal{F}(\text{tw}) &= e^{-i\pi(N-1)/2} \mathcal{F}(v)
\end{align*}
\]

is the Fourier transform of the series
\[
\begin{align*}
v_n &= \frac{1}{N} \left[ 1 - \cos \left( \frac{\pi}{2} \left( \frac{1}{2} + \frac{n}{N} \right) \right) \right] \quad n = 0, \ldots, N-1 \tag{3.22}
\end{align*}
\]
\[
= x_n, \quad \text{say}
\]

\]
(5.21) is called the "Hanned transform" of \( x_t \), and (5.22) shows that the alternative way to calculate \( \hat{J}(w) \) is to multiply \( x_t \) by \( z_t \) \( V_t \) and then to take the Fourier transform of the series. \( \{z_t\} \) is called a data window, and \( \hat{J}_H(w) \) the Fourier transform of the tapered data.

Usually, we would like the transform \( z_t \) to leave the majority of the data unchanged - since the Fourier transform of a tapered sinusoid is the Fourier transform of the data window \( \{z_t\} \) centred at the frequency of the sinusoid. So we only want to "taper" the extreme values in \( \{x_t\} \), i.e. the end values.

A convenient window that does this can be obtained from \( \{z_t\} \) by inserting \( I^s \) in the middle stretch of data - thus we are only tapering the ends. The new data window is then

\[
z_t^* = \begin{cases} 
\frac{1}{2} \left[ 1 - \cos \left( \frac{\pi}{N} (t - \frac{1}{2}) \right) \right] & t = 0, \ldots, k-1 \\
1 & t = k, \ldots, N-k-1 \\
\frac{1}{2} \left[ 1 - \cos \left( \frac{\pi}{N} (N - t - \frac{1}{2}) \right) \right] & t > N-k
\end{cases}
\]

and \( k \) is such that \( \frac{2k}{N} \) of the data is "tapered".

Tatey (1967) suggests that 10% or 20% tapering may be satisfactory.

5.7 SUMMARY

In this chapter, we have seen some of the problems associated with computing an estimate of the spectrum. \( \hat{S}_t \) does not assist in indicating model parameters (except that it does indicate dominant frequencies in the data, and thus can only be used like the periodogram). However, even considering the inherent problems in the periodogram (like leakage, failure of
the variance of periodogram estimates to decrease etc), in my opinion it is far easier to use the periodogram than the sdf (even though the periodogram is an unbiased, inconsistent estimate of the sdf).

The periodogram does not have the serious problems associated with the sdf mentioned above, and if tapering (section 5.4.2) is used some of the problems associated with leakage will be (in fact will be) eliminated to a large extent.

However, if one decides that a spectral estimate is necessary then it is probably best to use the Parzen window (b) (see (4.25)) and a range of truncation points, $\{W_i\}$ where $i = 1, 2, \ldots, 5$ say (see Priestley (1981), Weave (1972), Gottman (1981)).
6.1 INTRODUCTION

So far we have only been dealing with time-series in the frequency-domain i.e. we have been fitting models of the form

\[ y_t = \sum_{i=0}^{p} a_i \cos(\omega_i t) + \sum_{i=0}^{q} b_i \sin(\omega_i t) \]  \hspace{1cm} (6.1)

In the frequency-domain, the time-series is considered i.i.d. waves (i.e. cosine and sine functions) and the frequencies related to these waves. If the data are studied in terms of the auto-correlation function, then inferences based on this function are generally called an analysis in the time-domain.

If we assume that any oscillations of major frequencies (that explain variability in the time-series) have been removed (or 'modelled out') - that is if any such oscillations exist - we are left with a series of residuals \( \ldots \) \( b_1, b_2, \ldots \) (or the original series \( \ldots \) \( x_1, x_2, x_3, \ldots \)) where

\[ \epsilon_t = x_t - \sum_{i=0}^{p} a_i \cos(\omega_i t) - \sum_{i=0}^{q} b_i \sin(\omega_i t) \]  \hspace{1cm} (6.2)

Now it is certainly feasible that these residuals follow some model (assuming we are dealing with a stationary process)

\[ \begin{align*}
\epsilon_t &= \theta_1 \epsilon_{t-1} + \theta_2 \epsilon_{t-2} + \cdots + \theta_p \epsilon_{t-p} \\
\epsilon_t &= \phi_1 \epsilon_{t-1} + \epsilon_{t-2} + \phi_2 \epsilon_{t-2} + \cdots + \phi_p \epsilon_{t-p} \\
\epsilon_t &= \mu_t + \gamma_t
\end{align*} \]

(\( \epsilon_t \) = error terms)
In time-series analysis in the time-domain, the object is to try and find a model, based on inferences from the acrf, and then calculate its parameters.

The strategies which will be used here are the strategies formalized by Box and Jenkins (1970, 1976) and henceforth to be known as Box-Jenkins models (BJ models).

These models can be categorized into three classes

(i) autoregressive (AR) processes
(ii) moving average (MA) processes
(iii) mixed AR-MA processes (ARMA).

The form of these processes is given in the following definitions.

**Definition 15**

(i) The backward shift operator, $B$, is defined by

$$ X_{t-k} = x_{t-k} $$

where $k$ is a non-negative integer.

(ii) The inverse operation is defined by the forward shift operator, $F$, and is such that

$$ X_{t+k} = x_{t+k} $$

where $k$ is a non-negative integer.

**Definition 16**

The backward difference operator, $\Delta$, is defined by

$$ \Delta x_t = (1-B)x_t = x_t - x_{t-1} $$

and

$$ (1-B)^k x_t = \sum_{i=0}^{k} (-1)^i \binom{k}{i} x_{t-i-k} $$

where $k$ is some integer.

I have used the 2nd edition (1976) as my main source of reference for Box-Jenkins models.
Definition 17

An autoregressive process of order \( p \) (or AR(\( p \)) process), \( X_t \),
(where \( \{X_t\} \) is (second-order) stationary - see defn. 9, pg. 7 \((m=2)\))
is such that

\[
X_t = \phi_1 X_{t-1} + \cdots + \phi_p X_{t-p} + \eta_t
\]

where \( \mathbb{E}(X_t) = 0 \) (w.l.o.g) \( \forall t \) and \( \eta_t \) is a purely random process,
(i.e. white noise).

\[
\phi(B) = 1 - \frac{\phi_1}{B} - \cdots - \frac{\phi_p}{B^p} \quad (B = \text{backward shift operator} - \text{see defn. 15, pg. 102})
\]

then

\[
\phi(B)X_t = \eta_t \quad (6.3)
\]

Definition 18

A moving average process of order \( q \) (or MA(\( q \)) process), \( X_t \), is
such that

\[
X_t = a_t - a_{t-1} - \cdots - a_{t-q}
\]

where \( a_t \) and \( X_t \) are as in definition 17

If \( \theta(B) = 1 - \frac{\theta_1}{B} - \cdots - \frac{\theta_q}{B^q} \quad (B = \text{backward shift operator})

then

\[
x_t = \theta(B)a_t \quad (6.4)
\]

Definition 19

A mixed autoregressive - moving average process of orders \( p \) and \( q \) (or ARMA(\( p,q \)) process), \( X_t \), is such that

\[
\phi(B)X_t = \theta(B)a_t \quad (6.5)
\]

with \( \{X_t\}, a_t, \phi(B) \) and \( \theta(B) \) as in definitions 17 and 18.

From this point, \( X_t \) will be considered as the time-series irrespective of whether the original series has been analysed using spectrum analysis i.e. \( X_t \) is the end result of the spectrum analysis.
Definition 20

The covariance matrix associated with a stationary process \( \{ x_t \} \), which has realization \( \{ x_0, x_1, \ldots, x_{N-1} \} \), is given by

\[
\gamma = \begin{bmatrix}
\gamma(0) & \gamma(1) & \ldots & \gamma(N-1) \\
\gamma(1) & \gamma(0) & \ldots & \gamma(N-2) \\
\vdots & \vdots & \ddots & \vdots \\
\gamma(N-1) & \gamma(N-2) & \ldots & \gamma(0)
\end{bmatrix}
\]

where \( \gamma(i) \) is the acv at lag \( i \).

Note that

\[
\gamma = \frac{1}{N} \mathbf{X} \mathbf{P}_N \mathbf{X}^T
\]

where

\[
\mathbf{P}_N = \begin{bmatrix}
\xi(0) & \xi(1) & \ldots & \xi(N-1) \\
\xi(1) & \xi(0) & \ldots & \xi(N-2) \\
\vdots & \vdots & \ddots & \vdots \\
\xi(N-1) & \xi(N-2) & \ldots & \xi(0)
\end{bmatrix}
\]

where \( \xi(1) \) =acr at lag 1

and \( \xi(0) = 1 \) (and \( \frac{1}{N} \mathbf{X} \mathbf{P}_N \mathbf{X}^T \))

\( \mathbf{P}_N \) is called the autocorrelation matrix. Any acv or acr matrix for a stationary process \( \{ x_t \} \) is positive semi-definite and thus the determinant is always positive (unless the \( a_t \) = 0 \( \forall t \)).

[As in earlier chapters, \( \gamma \) and \( r_k \) will be used as estimates of \( \gamma(0) \) and \( \gamma(k) \)]

All three of these processes (i.e. AR, MA and ARMA) turn out to be special cases of the general linear process

Second-order stationary
In fact, Yule (1927), has shown that any (second-order) stationary process \( \{X_t\} \) may be expressed in the form (6.6.). Thus any AR(p) process can be expressed as an MA(\( \infty \)) process (and vice versa) — see, for example, T.W. Anderson (1971).

Due to these facts, the MA process will be considered now.

6.2 THE MA PROCESS

If \( \{X_t\} \) is an MA(q) process (where from now on, unless stated otherwise, \( \{X_t\} \) is assumed to be (second-order) zero-mean stationary, and \( q \) is finite), then by (6.4)

\[
X_t = \varphi(B)a_t \quad \forall t
\]

where

\[
\varphi(B) = 1 - \beta_1 B - \ldots - \beta_q B^q
\]

and \( a_t \) = white noise.

Note that if we 'know' \( \{a_t\} \), then for any \( 1, 2, \ldots, q \), \( X_t \) in (6.7) is stationary.

How do we estimate the \( \beta_1, \ldots, \beta_q \)?

What we really need are estimates of \( \beta_1, \ldots, \beta_q \) as well as some idea about \( a_t \) (since \( E(a_t) = 0 \) \( \forall t \)).

Firstly, suppose \( q = 1 \) i.e. we have an MA(1) process. Thus

\[
x_t = \sigma t - \beta_1 a_{t-1} \quad \forall t.
\]

Then \( \sigma^2 = E(x_t^2) = \beta_1 E(a_t^2) + \sigma^2 \).

Since \( \{a_t\} \) has zero-mean.
\[ Y(k) = \mathbb{E}(a_t \cdot a_{t-1}) \cdot (a_{t+k} \cdot a_{t+k-1}) \]

\[ = \mathbb{E}(a_t \cdot a_{t+k}) \cdot \mathbb{E}(a_{t-1} \cdot a_{t+k}) \]

\[ - \beta_1 \mathbb{E}(a_t \cdot a_{t+k-1}) \]

\[ + \frac{\delta_2}{1} \mathbb{E}(a_{t-1} \cdot a_{t+k-1}) \]

Setting \( k = 0 \),

\[ \gamma(0) = \frac{\sigma^2}{\alpha} \]

\[ = (1 + \delta_2 \frac{\sigma^2}{\alpha}) \]

since \( \gamma_a(k) = 0 \quad \forall k \neq 0 \)

(by definition of \( a_t^2 \))

For \( k = 1 \), it may be shown that \( \gamma(1) = \frac{\sigma^2}{\alpha} \) (due to the form of \( \gamma(k) \) and since \( \gamma_a(k) = 0 \quad \forall k \neq 0 \))

and if \( k > 1 \), \( \gamma(k) = 0 \)

It turns out that if \( \{X_t\} \) is an MA(q) process that

\[ \gamma(k) = 0 \quad \forall k > q \quad \text{(Box and Jenkins (1976))} \]

i.e. an MA(q) process has an acvf that truncates after lag \( q \).

Also,

\[ \gamma(k) = \mathbb{E}(a_t \cdot \sum_{j=1}^{q} a_{t-1} \cdot (a_{t+k} \cdot a_{t+k-1}) \cdot (a_{t-k} \cdot a_{t-k-1})) \]

thus if \( k = 0 \)

\[ \gamma(0) = \frac{\sigma^2}{\alpha} \]

\[ = (1 + \frac{\sigma^2}{\alpha}) \]

and in general (see Box and Jenkins (1976) pg.68)

\[ \gamma(k) = (-\delta_1^k \frac{\sigma^2}{\alpha}) \]

\[ = \frac{\delta_1^k \sigma^2}{\alpha} \]

\[ = \frac{\delta_1^k \sigma^2}{\alpha} \]

\[ \forall \alpha \leq q \]  

If we replace \( Y(k) \) by \( \bar{y}_k \) in (6.9) we have (q+1) nonlinear equations

for (q+1) unknowns, \( \bar{y}_k \). (Strictly speaking, \( \bar{y}_0 = 1 \) and so is not an unknown.)
6.3 THE AR PROCESS

If \{x_t\} is an AR(p) process then by (6.3)

\[ \phi(B) x_t = a_t \]

where \( \phi(B) = 1 - \phi_1 B - \ldots - \phi_p B^p \)

and \( \{a_t\} = \text{white noise series} \)

Again, as in section 6.2, we need to identify something about the AR(p) process in order to distinguish it from other processes (the MA(q) has acvf cut-off at lag q).

Consider the AR(1) process

i.e. \[ x_t - \phi x_{t-1} = a_t \]

Multiplying this by \( x_{t-k} \) and taking expectations gives

\[ \gamma(k) = \sum E(x_{t-k} x_{t-1}) = \text{cov}(x_{t-k}, a_t) \]

But \( \text{cov}(x_{t-k}, a_t) = 0 \) (since \( x_{t-k} \) depends only on \( a_{t-k}, a_{t-k-1}, \ldots \) which are uncorrelated with \( a_t \) provided \( k > 0 \))

\[ \gamma(k) = \gamma(k-1) \]

or \[ \gamma(k) = \gamma(1) \cdot 1 \]

hence

\[ \gamma(k) = \gamma(1)^k \]  \hspace{1cm} (if \( p = 1 \)) (6.9a)

and thus the correlogram of an AR(1) process does not truncate like an MA(1).

Now \[ x_t - \phi x_{t-1} = (1 - \phi B) x_t \]

\[ a_t = \psi(B) x_t \]

\[ a_t = (1 - \phi B)^{-1} a_t \]

(\( -\text{MA}(\infty) \) see, for example, Anderson (1971) or Yule (1927)) if \( |\phi| < 1 \)
V(x_t) = f(0)

which is finite only if \( |\phi_1| < 1 \)

So an AR(1) process is stationary only if \( |\phi_1| < 1 \) (unlike MA(q) processes which are stationary for all q).

6.3.1 THE YULE-WALKER EQUATIONS

Does some set of equations exist (as in the MA case) whereby for a general AR(p) process we can derive estimates \( \phi_i \) (i = 1, 2, ..., p)?

Suppose \( \{x_t\} \) is an AR(p) process, then

\[
x_t = \phi_1 x_{t-1} + \cdots + \phi_p x_{t-p} + \epsilon_t
\]

and

\[
\gamma(k) = E(x_t x_{t-k})
\]

But

\[
\gamma(k) = E(x_t x_{t-k}) = \sum_{j=1}^{p} \gamma(k-j) + \phi_k \gamma(0) - \phi_{k-p} \gamma(p)
\]

(If \( \epsilon_t \) is white noise, \( \gamma(k) = 0 \) if \( k < 0 \)).

Thus if \( k > 0 \)

\[
\gamma(k) = \sum_{j=1}^{p} \gamma(k-j) + \phi_k \gamma(0) - \phi_{k-p} \gamma(p)
\]

and if \( k = 0 \)

\[
\gamma(0) = \gamma(0) = \phi_1 + \cdots + \phi_p - \phi_{p-1} - \cdots - \phi_1
\]

But

\[
\gamma(k) = \gamma(-k)
\]

and

\[
E(a_t x_t) = E(a_t (\phi_1 x_{t-1} + \cdots + \phi_p x_{t-p} + \epsilon_t))
\]

\[
= E(a_t^2)
\]

\[
= \sigma^2
\]
\[ (6.11) \]

\[ \psi(0) = \begin{bmatrix} \gamma_2 & \gamma_3 & \cdots & \gamma_p \end{bmatrix} \]

\[ \phi_1 z_1(p) + \cdots + \phi_p z_p(p) = \begin{bmatrix} \gamma_2 & \gamma_3 & \cdots & \gamma_p \end{bmatrix} \]

and hence

\[ \gamma_2 \ldots \gamma_p = \gamma_0 (1 - \phi_1 - \cdots - \phi_p(p)) \]

Thus if we know the value of \( p \), we can use (6.10) and (6.12) to estimate \( \phi_1, \phi_2, \ldots, \phi_p \).

The equations (6.10) for \( k = 1, 2, \ldots, p \) are known as the Yule-Walker (Y-W) equations.

(Note that AR processes are easier to work with than MA processes due to the linearity of the Y-W equations.)

6.3.2 THE DUALITY BETWEEN AN MA(1) AND AN AR(1)

Suppose \( \chi_t \) is an MA(1) process then

\[ \chi_t = \theta \chi_{t-1} + a_t \]

and so

\[ \chi_{t-2} = \theta \chi_{t-3} + \theta^2 a_{t-2} \]

\[ a_{t-1} = \theta \chi_{t-2} + \theta^2 a_{t-2} \]

thus

\[ x_t = \theta x_{t-1} + \theta^2 x_{t-2} \]

But

\[ x_{t-2} = \theta x_{t-3} + \theta^2 x_{t-4} \]

so

\[ x_t = \theta x_{t-1} + \theta^2 x_{t-2} = \theta x_{t-2} + \theta^2 x_{t-3} \]

Now provided \( x_1 \sim N(0,1) \), then we may write
But $\beta_1^k = 0$ only if $|\beta_1| < 1$ thus an MA(1) may be written as an AR($\infty$) provided $|\beta_1| = 1$. This condition is termed an invertibility condition (and this is the same as the stationarity condition for an AR(1)).

This is also true for the general case (by induction we may show that the stationarity conditions of an AR(2) are identical with the invertibility conditions of an MA(2) etc. Also see section 6.3.1.)

What are the implications of all this? An MA(1) may be approximated by a high order AR process and an AR(1) by an MA(q) (q large). Similarly for MA(2) and AR(2).

### 6.3.3 The AR(2) Process

Suppose $X_t$ is an AR(2) process. Then

$$X_t = \alpha X_{t-1} + \gamma X_{t-2} + \epsilon_t$$

By section 6.3.1 (i.e. equation (6.10))

$$(1) = \beta_1 (1) - \beta_2 (2)$$

or

and

$$\begin{align*}
(1) &= \beta_1 (1) - \beta_2 (2) \\
(2) &= \gamma (1) - \alpha (2) - \beta_2 (2) \\
&= \gamma (1) - \beta_2 (2) \\
&= \gamma (1) - \beta_2 (2)
\end{align*}$$

$$\begin{align*}
(1) &= \beta_1 (1) - \beta_2 (2) \\
(2) &= \gamma (1) - \beta_2 (2) - \gamma (1)
\end{align*}$$

and

$$\begin{align*}
(1) &= \beta_1 (1) - \beta_2 (2) \\
(2) &= \gamma (1) - \beta_2 (2) - \gamma (1)
\end{align*}$$

or

$$\begin{align*}
(1) &= \beta_1 (1) - \beta_2 (2) \\
(2) &= \beta_1 (1) - \beta_2 (2) - \gamma (1)
\end{align*}$$

and

$$\begin{align*}
(1) &= \beta_1 (1) - \beta_2 (2) \\
(2) &= \beta_1 (1) - \beta_2 (2) - \gamma (1)
\end{align*}$$

These equations represent the relationships between the parameters of the AR(2) process. The stationarity and invertibility conditions ensure that these equations hold.

The implications of these equations are that the AR(2) process can be approximated by a high order MA(q) process and vice versa, with the conditions $|\beta_1|, |\beta_2| < 1$ ensuring stationarity and invertibility.
Now \( |\phi(1)| \leq 1 \)

and \( |\phi(2)| \leq 1 \)

Also
\[
\frac{\phi_1^2 - \phi_2^2}{\phi_1^2 - \phi_2^2} = 1 - (1 - (1) \phi_1 - (2) \phi_2) \quad \text{(by (6.12))}
\]

(6.13a)

and substituting here for \( \phi(1) \) and \( \phi(2) \) from the equations (6.12b),
after some algebra it may be shown that
\[
\frac{\phi_1^2}{\phi_2^2} = \frac{1 - \phi_2^2}{\phi_1^2 - \phi_2^2} (1 - (1 - \phi_2^2)(1 + \phi_1^2 - \phi_2^2)) \quad \text{(6.13b)}
\]

Thus, since \( \frac{\phi_1^2}{\phi_2^2} > 0 \)

and \( |\phi(1)| \leq 1 \quad \forall i \)

then each factor in \( \frac{\phi_1^2}{\phi_2^2} \) must be greater than, or equal to, zero

hence
\[
-1 < \phi_2 < 1
\]

\[
\phi_2 = \frac{\phi_1^2}{\phi_2^2} \quad \text{(from (6.12b))}
\]

\[
\phi_2 = \frac{\phi_1^2}{\phi_2^2} < 1
\]

These are the stationarity conditions for an AR(2) process, hence

the invertibility condition for an MA(2) will be identical

(provided \( \phi_1 \) is replaced by \( \phi_2 \) and \( \phi_2 \) by \( \phi_2 \)).

The following figures show the form of the acf for various values of \( \phi_1 \) and \( \phi_2 \) in the AR(2) process

\[\text{Fig 6.1}\]

For more detail see Box and Jenkins (1976), pg. 34
Note that in all four cases here, the acrf dies out (slowly).

Also note that in two cases the acrf has cyclical form even though the \( R(2) \) process itself is not cyclical.
6.4 THE PARTIAL AUTOCORRELATION FUNCTION (PACRF)

So far we have seen that it is possible to identify an MA(q) process from the acrf alone (if the acrf has cut-off after lag q). However this is not true for the AR(p) process. What we really require is some function which may be used in a similar way to identify p in an AR(p) process. Such a function exists and is known as the partial autocorrelation function (pacrf). This function completes the 'duality' between the MA and AR processes - the AR(p) process has cut-off after lag p and the MA(q) process dies out. The form of the pacrf and a proof that it can be used to identify p, is given below.

Consider the AR(1) process given in section 6.3. We know that 

\[ c(k) = \frac{1}{\lambda^k} \]  

(see (6.9a))

so observations one lag apart have a correlation of \( \lambda \) and observations two lags apart a correlation of \( \lambda^2 \) i.e. observations \( x_{t-1} \) have a correlation with \( x_t \). The question: "Is \( x_{t+3} \) independent of \( x_{t+1} \) given \( x_{t-2} \) can be answered by the partial correlation \( \rho_{1,3|2} \) where \( \rho_{1,3|2} \) is the correlation of \( x_{t+1} \) with \( x_{t+3} \) given \( x_{t+2} \) (or conditional on \( x_{t+2} \)). \( x_{t+3} \) is independent of \( x_{t-1} \) if \( \rho_{1,3|2} \) is zero.

Now, after some algebra, it may be shown that

\[
-1.3^{-2} = \frac{1-\lambda^{-2}}{(1-\lambda^{-1})(1-\lambda^{-2})}
\]

(see, for example, Gottman (1981))
where \( \rho_{i,j} = \rho(i - j) \).

But
\[
\rho_3 = \rho(2) = \rho_1^2
\]
and
\[
\rho_2 = \rho(1) = \rho_1
\]
and thus
\[
\rho_{1,3|2} = 0
\]
i.e. there is no relationship between \( x_{t-1} \) and \( x_{t-3} \) once the intermediate association with \( x_{t-2} \) is removed. Similarly, all higher order partial correlations are also zero. So for an AR(1) process the partial correlations are zero after lag one.

Consider the AR(2) process given in section 6.3.3. After algebraic manipulation it may be shown that
\[
\rho_{1,3|2} = \frac{\rho(2) - \rho(1)^2}{1 - \rho(1)^2} = \rho_2
\]
(see Gottman (1981)) and so, all higher order partial correlations (e.g. \( \rho_{1,4|3} \)) are zero (Box and Jenkins (1976)). Thus for an AR(2) process, the pacrf at lags 1 and 2 is nonzero, but is zero at all other lags.

Also note that the final nonzero partial correlation takes the value of the highest AR coefficient (i.e. \( \rho_2 \)) as in the AR(1) case. (This result holds in general for an AR(p) process - see, for example, Box and Jenkins (1976)).

Denote \( \rho_{1,i} \) as the \( i \)th AR coefficient in an AR(\( i \)) process. A plot of \( \rho_{1,i} \) against \( i \) is termed the pacrf. The pacrf just tells us that if an AR(k-1) process has been fitted, then \( \rho_{kk} \) is the 'gain' (or extra information) acquired by fitting an AR(k).

Obviously if \( \rho_{1,i} \) is really an AR(j) process then \( \rho_{(j+1, j+1)} = 0 \) i.e. the cut-off point is 'lag j.'
Since any MA(q) process may be written as an AR process - see for instance Yule (1927) - then the pacrf of an MA(q) does not truncate after lag q (in fact it will have a pacrf of the same form as the acrf of an AR process).

Quenouille (1947) has shown that if $X_t$ is an AR(p) process then $\varphi_p(j > p)$ has approximate variance of $1/N$ (where $N$ is the number of observations in the time-series).

6.5 ARMA PROCESSES AND THE SDF OF BOX-JENKINS MODELS

6.5.1 ARMA PROCESSES

By definition 19, if $X_t$ is an ARMA(p,q) process then

$$ \phi(B)x_t = \theta(B)\epsilon_t $$

where $\phi(B) = 1 - \phi_1B - \ldots - \phi_pB^p$

and $\theta(B) = 1 - \theta_1B - \ldots - \theta_qB^q$

Since $X_t$ has both an AR and an MA component, the acrf and pacrf are 'mixtures' of the functions for AR and MA processes.

The acvf satisfies

$$ \gamma(k) = \phi_1\gamma(k-1) + \ldots + \phi_p\gamma(k-p) + \epsilon(t)\epsilon(t-k) + \epsilon(t-k)\epsilon(t-k-1) $$

where $\phi(B) = 1 - \phi_1B - \ldots - \phi_pB^p$

(see Box and Jenkins (1976) pg. 74)

Define

$$ \gamma_{xy}(k) = \text{cross covariance function between } x_t \text{ and } y_t $$

(6.15)
then

\[
\begin{align*}
\phi_a(k) & = 0 \quad k > 0 \\
\psi_a(k) & = 0 \quad k < 0
\end{align*}
\]

(6.16)

If \( k > q + 1 \), then (6.14) implies

\[
\phi_a(k) = \phi_1(k-1) + \ldots + \phi_p(k-p)
\]

and hence \( \psi_a(k) = 0 \)

\[
\psi_a(k) = 0 \quad (k > q)
\]

(6.16a)

When \( k = 0 \), the variance of the process is

\[
\Psi(0) = \sum_{i=1}^{q} \phi_i \psi_a(i - 1) - \sum_{i=0}^{q} \phi_x i a
\]

(6.17)

6.3.2 THE SPECTRA OF AR, MA AND ARMA MODELS

Recall from section 5.4.1 that if

\[
y_t = \sum_{u=1}^{p} a_u x_{t-u} + v_t
\]

then

\[
h_y(w) = \text{sdf of } Y_t
\]

\[
= |A(w)|^2 h_x(w)
\]

\[-\pi < w < \pi
\]

(6.18)

where

\[
h_x(w) = \text{sdf of } X_t
\]

and

\[
A(w) = \sum_{u=1}^{p} a_0 e^{-iuw}
\]

Now if \( |X_t| \) is an AR(p) process then

\[
\gamma(B) x_t = a_t + v_t
\]

\[
\gamma(B) = 1 - \phi_1 B - \ldots - \phi_p B^p
\]

\([a_t] = \text{white noise process}

\[
\gamma(B) a_t = 0 + \sum_{j=0}^{p-1} a_j x_{t-j} + v_t
\]

and
h_j(w) = \|h_j(w)\|^2 \delta_j(w) - \pi \leq w \leq \pi \text{ by (6.18)}

where

\delta_j(w) = 1 - \frac{p}{j=1} \delta_j e^{-ijw}

i.e.

\hat{h}_j(w) = \frac{h_j(w)}{\|\delta(w)\|^2}

But

h_j(w) = \sum_{j=1}^{p} \gamma(t) \cos(tw) \text{ by definition}

and

\gamma(t) = \begin{cases} 0 & t > 0 \\ \frac{2}{\pi} & t = 0 \\ \end{cases} \quad \text{by definition of white noise}

and

\sum_{j=1}^{p} e^{-ijw} = 1 - e^{-iw} - \cdots - \frac{e^{-ipw}}{2}

so the sdf of an AR(p) process is given by

h(w) = \sum_{j=1}^{p} \frac{\gamma(t)}{2\pi} e^{-ijw} \quad -\pi \leq w \leq \pi \quad \text{(6.19)}

If \gamma(t) is an MA(q) process then

\gamma(t) = \theta(B)\epsilon_t

where \theta(B) = 1 - \theta_1B - \cdots - \theta_qB^q

thus

h_x(w) = \|h_x(w)\|^2 h_a(w)

where

h_a(w) = 1 - \frac{q}{j=1} \theta_j e^{-ijw}
Similarly, if \( \{X_t\} \) is an ARMA(\( p, q \)) process then

\[
h_X(w) = \frac{\sum_{j=1}^{2} \left| 1 - \frac{1}{a_j} e^{-ijw} \right|^2}{2\pi \sum_{j=1}^{2} \left| 1 - \frac{1}{a_j} e^{-ijw} \right|^2} \tag{6.21}\]

The form of the theoretical spectrum is easily calculated for any of these processes provided the model parameters are known. Even if the parameters are unknown, but we have estimates thereof, then we may plot the spectrum of \( \{X_t\} \) using the parameter estimates and then compare this spectrum with the spectrum (estimate) of the original data.

### 6.6 A GENERAL NOTE ON STATIONARITY AND INVERTIBILITY

Consider the general linear process \( \{X_t\} \) defined in (6.6)

\[
x_t = \sum_{j=d}^{\infty} \phi_j a_{t-j} \quad \forall t \quad \gamma_0 = 1
\]

\[
\gamma(k) = \sum_{j=0}^{L} \phi_j \gamma_{k+j} \tag{6.22}\]

where \( \phi = \) backshift operator

\[
\phi(B) = 1 + \phi_1 B + \phi_2 B^2 + \ldots
\]

and \( \{a_t\} \) = white noise process

Thus

\[
a_k(\gamma) = \begin{cases} 1 & \text{if } k = 0 \\ 0 & \text{otherwise} \end{cases}
\]

\[
\phi_k = \begin{cases} 1 & \text{if } k = 0 \\ 0 & \text{otherwise} \end{cases}
\]
and \[ a(k) = \begin{cases} 0 & \text{if } k < 0 \\ 1 & \text{if } k = 0. \end{cases} \]

Note that
\[
\begin{aligned}
x_t - \beta_1 x_{t-1} &= a_t - \beta_1 a_{t-1} + \sum_{j=1}^{\infty} \beta_1^j a_{t-1-j} \\
&= a_t + (\beta_1 - 1) a_{t-1} + \sum_{j=1}^{\infty} \beta_1^j a_{t-1-j}
\end{aligned}
\]
where \( \beta_j = \beta_1^j - \beta_1^{j-1} \)
and choosing \( \beta_1 = 1 \) \( \beta = 0 \)

i.e. \( \beta_1 = \beta_1 = 1 \) say

thus
\[
x_t - \beta_1 x_{t-1} = a_t + \sum_{j=2}^{\infty} \beta_1^j a_{t-1-j}
\]

Similarly
\[
\begin{aligned}
x_t - \beta_1 x_{t-1} - \beta_2 x_{t-2} &= a_t + \sum_{j=2}^{\infty} \beta_2^j a_{t-2-j} - \beta_2 a_{t-2} - \sum_{j=3}^{\infty} \beta_2^j a_{t-2-j}
\end{aligned}
\]

Again we may choose \( \beta_2 = 1 \)

i.e. \( \beta_2 = 1 \) say

\[ \beta_2 = \beta_1 \]

Continuing in this manner we eventually obtain
\[
\begin{aligned}
x_t &= \sum_{j=1}^{\infty} \beta_j x_{t-j} = a_t \\
or
\begin{bmatrix} x_t \\ x_{t-1} \end{bmatrix} &= \begin{bmatrix} A_1 & A_2 \\ 0 & A_1 \end{bmatrix} \begin{bmatrix} x_{t-1} \\ x_{t-2} \end{bmatrix} = a_t
\end{aligned}
\]

Writing \( -(B) = 1 - \sum_{j=1}^{\infty} \beta_j \)
Thus \( \pi(B)x_t = \alpha_t \)

But \( x_t = \pi(B)\alpha_t \)

Thus \( \pi(B) = (\pi(B))^{-1} \) \( (6.23) \)

(B now a dummy variable)

Thus if \( \{x_t\} \) is stationary, we may write an MA(\( \infty \)) as an AR(\( \infty \)).

Now

\[
\gamma_X(k) = E(x_t x_{t-k})
\]

\[
= \sum_{j=0}^{\infty} \alpha_j^2 \delta_{k-j} = \sum_{j=0}^{\infty} \alpha_j^2 \delta_{k-j}
\]

\[
\gamma_X(0) = 1
\]

and for \( k = 0 \), \( \gamma_X(0) = \frac{2}{\pi} \)

\[
\gamma_X(k) = \frac{2}{\pi} \sum_{j=0}^{\infty} \frac{\alpha_j^2}{j+k+1}, \quad (i_0 = 1) \quad (6.25)
\]

Thus the \( \alpha \) weights must decrease fast enough to ensure that \( |x_t| \) has a finite variance, or more specifically, \( \sum_{j=0}^{\infty} \frac{\alpha_j^2}{j+k+1} \) must converge

Define

\[
\gamma(B) = \sum_{k=-\infty}^{\infty} \gamma_X(k)B^k
\]

(called the autocovariance generating function)

then

\[
\gamma(B) = \frac{1}{\pi} \theta(B) \theta(F)
\]

(6.27)

where \( F = \) forward shift operator.

((6.27) is obtained after substituting (6.24) in (6.26) - see Box and Jenkins (1976), pg. 81).

\( I_X(w) \), the sample periodogram of \( \{x_t\} \) is defined by

\[
I_X(w) = \frac{1}{2\pi} \sum_{k=1}^{N} \alpha_k \cos(\omega k) \quad -\pi < \omega < \pi
\]

(see section 4.1)

and \( \lim_{N \to \infty} E(I_X(w)) = h_X(s) \) the sdf

\[
\hat{h}_X(s) = 2f(x)
\]

where \( f(x) \) is the nsdf
Replacing $B$ by $e^{-1w}$ in (6.26) gives

$$
\Gamma(e^{-1w}) = \sum_{k=-\infty}^{\infty} X(k) e^{-1wk}
$$

$$
= \lim_{a \to \infty} \frac{2}{\pi} \hat{h}(w) e^{-1w} \text{ since } F = B^{-1} \text{ (see defn. 15)}
$$

i.e. $\Gamma(e^{-1w}) = \frac{1}{\pi} \int_{-\pi}^{\pi} \hat{h}(w) e^{-1w} dw$

$$
\hat{h}(w) = \frac{1}{\pi} \left| X(e^{-1w}) \right|^2
$$

Now

$$
\hat{h}(0) = \frac{\pi}{\pi} \int_{-\pi}^{\pi} h(w) dw \text{ by definition}
$$

and so $\frac{\pi}{\pi}$ is finite only if $\Gamma(B)$ converges - which occurs only when $B < 1$.

If $\Gamma(B) = 1 - B - \cdots = B^q$, i.e. $X_t$ is an MA(q) process, we still require $B < 1$ or equivalently we may ask that $\Gamma(B)$ has weights $\frac{1}{q}$ such that $\Gamma(B)$ converges on or within the unit circle. Similarly for $\Gamma(B)$.

Thus we have shown, more formally, the 'equivalence' of stationarity and invertibility conditions for AR and MA processes respectively (since AR and MA processes are just special cases of a general linear process and since $\Gamma(B) = (\Gamma(B))^{-1}$ and vice versa).

Strictly speaking, $\Gamma$ is only an operator, so $B < 1$ has no real meaning. $B$ must be considered as a dummy variable.
6.7 NOTES ON THE APPENDICES A9-A11

Appendix A9 gives a procedure, suggested by Box and Jenkins (1976), for obtaining 'initial' estimates in an ARMA \((p,q)\) process \((\text{given } p \text{ and } q)\). A10 provides a recursive method for calculating the \(\text{pacrf}\).

In A11, the properties (i.e. variance, acrf, pacrf etc) of the 'main' BJ models are given. These 'main' models are the \(\text{AR}(1)\), \(\text{AR}(2)\), \(\text{MA}(1)\), \(\text{MA}(2)\) and \(\text{ARMA}(1,1)\) processes. Also provided are the covariance matrices.

Anderson (1977) has also derived an iterative procedure for calculating parameter estimates (given the order of the model i.e. \(p\) and \(q\)) in both the frequency and time-domains. These procedures are in matrix form and may be applied to any realization \(x_0, x_1, \ldots, x_{n-1}\).
CHAPTER 7: THE BOX-JENKINS STRATEGY

Box-Jenkins modelling, or the Box-Jenkins strategy, consists of five phases, namely

(i) inducing stationarity
(ii) identification of the model
(iii) estimation of model parameters
(iv) checking the fit of the model
(v) forecasting

In this chapter, the first four phases will be dealt with in detail and a note made of the fifth.

7.1 PHASE ONE: INDUCING STATIONARITY

If our original series was \( Y_t \) (not necessarily stationary), then once the harmonic components (if any) have been removed, we are left with a set of residuals, \( Z_t \) say. Now these \( Z_t \) may be stationary or nonstationary. However, we saw in the last chapter that BJ models may only be applied to (second order) stationary processes. Thus the first stage of the BJ strategy consists of checking the condition of the residuals \( Z_t \).

If \( Z_t \) is a stationary process then we may proceed directly to phase two. However, if \( Z_t \) is nonstationary, we would like to transform the data (i.e. \( Z_t \)) into a stationary process \( X_t \).

Time-series, like any stochastic process, may be nonstationary in various ways. However, in section 6.6, when considering an ARMA \((p,q)\) process \( X_t \).
i.e. \( \phi(B) x_t = \theta(B) a_t \)

where \( \phi(B) = 1 - \phi_1 B - \ldots - \phi_p B^p \)
\( \theta(B) = 1 - \theta_1 B - \ldots - \theta_q B^q \)

\( \{ a_t \} = \) white noise process

To ensure stationarity, we required that the roots of \( \phi(B) = 0 \) lie outside the unit circle. (Similarly to ensure invertibility, we required that the roots of \( \theta(B) = 0 \) lie outside the unit circle).

Thus any process which has roots of \( \phi(B) = 0 \) lying inside the unit circle, is nonstationary. The process will also be nonstationary if the roots lie on the unit circle. Since the behaviour of the process is ‘explosive’ if the roots fall (strictly) inside the unit circle (see, for instance, Box and Jenkins (1976), p.88), we shall only consider the case where roots fall either on or outside the unit circle.

So consider the model

\[
\phi(B) z_t = \theta(B) a_t \quad \forall t
\]  

(7.1)

where \( \phi(B) = 0 \) has \( d \) roots, say, lying on the unit circle, and the rest outside.

We may rewrite (7.1) as

\[
\phi(B) z_t = (1 - B)^d \phi(B) z_t
\]

\[= \theta(B) a_t \quad (7.2)\]

where \( \phi(B) \) has all roots outside the unit circle.

But \( (1-B)^d \phi(B) = \phi(B)(1-B)^d \)

and \( \theta = 1 - B \) (see definition 16 of section 6.1)

i.e. the process is fluctuating wildly with no pattern
Thus

\[(1-B)^d \psi(B) z_t = \varphi(B)(1-B)^d x_t \]

= \varphi(B)x_t \quad \text{say (where } x_t = \psi(B) z_t) .

Now \( (X_t) \) is a stationary process since \( \varphi(B) \) has all its roots outside the unit circle and so it has an ARMA\((p,q)\) representation.

\( \psi(B) \) is called a stationary AR operator and \( \varphi(B) \) a nonstationary AR operator.

Note that \( x_t = \psi(B) z_t \) is just the \( d \)th successive 'difference' of \( z_t \).

Representation (7.2) is called an ARMA\((p,d,q)\) process (AR integrated MA) if \( d > 0 \) (otherwise it is just an ARMA\((p,q)\) process).

So, if we are given any process \( \psi(B) z_t \), we must determine \( d \) in order to be sure that

\[ \psi(B)^d z_t = x_t \]

is stationary \( x_t \).

If \( d \) is made too large, we may overdifference the data and possibly introduce meaningless patterns into the transformed series.

So care must be taken when deciding on the size of \( d \).

What indication is there that \( x_t \) may be nonstationary? In section 6.5 (specifically (6.16a)) it was shown that if \( x_t \) is an ARMA\((p,q)\) process then

\[ \varphi(B) \left( 1 - s_i B \right) = 0 \quad k > q \quad (7.3) \]

Now if \( \varphi(B) \) is a stationary AR operator (i.e. all roots of \( \varphi(B) = 0 \) lie outside the unit circle) then we may write

\[ \varphi(B) = \prod_{i=1}^{p} \left( 1 - s_i B \right) / \prod_{i=1}^{p} \left( 1 - S_i \right) \]

where \( s_i \) are the roots of \( \varphi(B) = 0 \). Hence

\[ \prod_{i=1}^{p} \left( 1 - S_i \right) \varphi(B) = 0 \quad \text{for} \quad k > q \]
If the $s_j$ are distinct (i.e. $s_j \neq s_k \forall i \neq j$) then the solution of the difference equation (7.3) is of the form

$$P(k) = \sum_{j=1}^{q-p} s_j^k = \sum_{j=1}^{q-p} s_j^k \quad (k > q - p) \quad (7.4)$$

(by the theory of linear difference equations - see, for instance, Box and Jenkins (1976), pp. 116). Since the roots of $\phi(B) = 0$ all lie outside the unit circle, then this implies that $|s_j| < 1 \forall i$, thus (7.4) tends rapidly to zero as $k$ increases.

If just one of the roots, $s_j = 1$ say, tends to unity (i.e. $s_j^{-1} = 1 - \epsilon > 0$) then if $k$ is large

$$P(k) = \sum_{j=1}^{q-p} s_j^k + \text{terms tending rapidly to zero}$$

and so the acrf does not die out quickly.

Thus an indication of non-stationarity is the acrf not dying out quickly.

Using the sample acrf as an estimate of the theoretical acrf, we may ascertain the stationarity or nonstationarity of a process.

If we conclude $\phi(B)$ is non-stationary then it must be differenced $d$ times (unless some of the roots lie inside the unit circle - i.e. the series shows explosive behaviour) i.e. find $\phi(B)^d = \phi_0$

What value should $d$ take?

Box and Jenkins (1976) suggest that $d$ is invariably either 0 or 1 or 2 (see Box and Jenkins (1976) pg. 173). So difference once, and if the acrf of the resulting series dies out 'quickly' we have
obtained stationarity. If not, carry on differencing until the acrf of the resulting series does in fact die out.

Gottman (1981, pg.262) has suggested that for each d, you calculate

\[
D_d = \sum_{k=0}^{N^*} \phi (k,d)
\]

(7.5)

where \( \phi (k,d) \) is the acrf of the \( d^{th} \) differenced series

and \( N^* = N/6 \) (this is in order to be able to compare the \( D_d \) across different values of \( d \)).

Estimate \( D_d \) by \( D_d’ \) (replace \( \phi (k,d) \) by \( r_{k,d}^2 \)) and then choose that value of \( d \) which gives a minimum value for \( D_d’ \).

Hill and Woodworth (1980) suggest using that value of \( d \) which minimizes

\[
\sum_{k=0}^{N^*} \phi (k,d)
\]

i.e.

\[
\min_d \left\{ \sum_{k=0}^{N^*} \phi (k,d) \right\} \]

(7.6)

Instead of using (7.5) or (7.6), it may be possible to determine when the (sample) acrf has effectively died out, by noting that

\[
V(r_{k}^2) = \frac{1}{N} \sum_{t=1}^{N} \left\{ \frac{2}{2} (t) - \phi(t-k) \phi(t-k) - 4 \phi(t-k) \phi(t-k) \right\}
\]

(7.7)

if \( X_t \) is a Gaussian process (as in A3.3), appendix A3).

If the acrf has died out after lag \( v \) say, then (7.7) may be rewritten as

The sample acr - see sections 2.4 and 2.5 (pages 33 and 37 resp.)
\[ V(r'_k) = \frac{1}{N} \left( 1 + 2 \sum_{i=1}^{v} c^2(i) \right) \quad k > v \] (7.8)

thus

\[ V(r'_k) = \left( 1 + 2 \sum_{i=1}^{v} r_i^2 \right) \quad k > v \] (7.9)

[So, for example, if \( X_t \) is a (Gaussian) white noise process, then \( v = 0 \) (by definition of the acrf of a white noise process) and

\[ \sqrt{V(r'_k)} = \sigma(r'_k) \text{ say} \] (7.10)

\[ \frac{1}{\sigma} \] = standard error]

Using (7.9), or (7.10), each lag in the (sample) acrf may be tested (successively) for a significant deviation from a zero value (since \( H_0: \gamma(k) = 0 \quad k > v \)

and thus

\[ \frac{r'_k}{\sqrt{V(r'_k)}} \sim N(0,1) \] using the normal approximation to the distribution of \( r'_k \); see Anderson (1942)). However the problem with this technique is the effect of multiple testing on the overall significance level.

7.2 PHASE TWO: IDENTIFICATION OF THE MODEL

Having induced stationarity by phase one, we are left with a (second-order) zero-mean stationary process \( \{ X_t \} \), and thus all the techniques from chapter six are available
We now wish to ascertain (i.e. estimate) the values of $p$ and $q$ in the ARMA($p,q$) model

$$\phi(B)x_t = \theta(B)a_t.$$ 

If $p = q = 0$ then $x_t = a_t$ always (i.e. $X_t$ is a white noise process) and all we need now do is check the fit of the model (i.e. the 'whiteness' of the residuals). Otherwise we must estimate $p$ and $q$ and hence the parameters in $\phi(B)$ and $\theta(B)$.

In chapter six, we saw some of the properties of the acrf and pacrf for AR, MA and ARMA processes. Recapping briefly, these were:

(a) the AR($p$) has cut-off after lag $p$ in the pacrf

(b) the MA($q$) has cut-off after lag $q$ in the acrf.

(c) if $X_t$ is an ARMA($p,q$) (where $p$ and $q$ are both nonzero) then the acrf and pacrf do not have cut-off points.

(d) an AR($p$) does not truncate in the acrf and neither does an MA($q$) in the pacrf.

Thus if both the acrf and the pacrf tail off, an ARMA($p,q$) is suggested, otherwise the form of the acrf or pacrf should suggest whether an AR($p$) or MA($q$) is likely. It is possible to ascertain a cut-off in the acrf by making use of the $V(r_k)$ (i.e. (7.9)).

Truncation in the pacrf is "determined" by noting that

$$V(\hat{\sigma}_{kk}) = \frac{1}{N} \quad k > p$$

(7.11)

If $X_t$ is an AR($p$) process (see Quenouille (1949)), thus

$$\hat{\sigma}_{kk} / \sqrt{n(0,1)}$$

where

$$\hat{\sigma}_{kk} = \sqrt{\hat{\sigma}_{kk}}$$

(see the final paragraph on pg. 114 for a definition of $\hat{\sigma}_{kk}$).
If \( \{X_t\} \) is an ARMA \((p,q)\) process with both \( p \) and \( q > 0 \), then the number of anomalous (i.e. not a mixture of exponential decay and damped sine waves) terms in the acrf is \( q - p \), and the number of anomalous terms in the pacrf is \( p - q \) (see Box and Jenkins (1976), pg. 186). Note that \( c(k) = c(-k) \), so the case when \( p-q \) (or \( q-p \)) is negative is no problem. The number of anomalous terms only gives an idea of the difference between \( p \) and \( q \) and not about their actual sizes. In practice, both \( p \) and \( q \) are usually \( \leq 3 \).

### 7.2.1 THE INVERSE ACRF AND INVERSE PACRF

Another tool useful in the identification of \( p \) and \( q \) in an ARMA\((p,q)\) process is the inverse autocorrelation function (iacrf) and analogously the inverse partial autocorrelation function (ipacr) (or similarly the iacvf and ipucvf).

If \( X_t \) is stationary with acvf \( \gamma(k) \) and acrf \( c(k) (k = 0, 1, ...) \), then the autocovariance generating function (acvgf) is defined by

\[
\Gamma(Z) = \sum_{k=-\infty}^{\infty} \gamma(k)Z^k
\]

and the autocorrelation generating function (acrgf) is defined by

\[
P(Z) = \sum_{k=-\infty}^{\infty} c(k)Z^k
\]

Then the inverse acvgf (iacvgf) is defined by \( I(Z) \) where

\[
\Gamma(Z)I(Z) = 1
\]

The coefficient in \( I(Z) \) of \( Z^{-k} \) is defined to be the inverse acv coefficient at lag \( k \) (and is denoted by \( \gamma_i(k) \)).

Similarly the inverse acrgf (or iacrgf) is defined by \( P(I(Z)) \) where
\[ P(Z)P(Z) = 1 \quad (7.15) \]
and the coefficient of \( Z^k \) in \( P(Z) \) is the inverse acr coefficient at lag \( k \) (and denoted \( I(k) \)).

Also
\[ \gamma I(k) = \gamma I(0) \quad (7.16) \]
thus
\[ P(Z) = \frac{\gamma I(Z)}{\gamma I(0)} \quad (7.17) \]
and
\[ P(Z)P(Z) = \left[ \gamma I(0) \right]^{-1} = 1 \quad (7.18) \]
(since \( P(Z)P(Z) = \left[ \gamma I(0) \right]^{-1} \) but \( \gamma I(0) = \gamma I(0) \) and
\[ I(0) = I(0) \]
where in general \( I(0) < \left[ \gamma I(0) \right]^{-1} \)
(and in fact \( \gamma I(k) = \gamma I(k) \) in general)

Now if \( \gamma(B)x_t = \gamma(B)a_t \quad (7.19) \)
then we may write (see, for example, section 6.6)
\[ x_t = \gamma(B)a_t \quad vt \]
where
\[ \gamma(B) = \gamma(B) \gamma(B) \quad (7.20) \]
so, by section 6.6 (and specifically by (6.27), it may be shown
that the acvdf of \( x_t \) is
\[ \Gamma Z = \gamma(Z) \gamma(Z) \gamma(1) \]
Thus the iscr \( \gamma \) of (7.19) are just the acr \( \gamma \) of the inverse model
of (7.19) i.e. the acr \( \gamma \) of
\[ \gamma(B) \gamma(B) = \gamma(B) \gamma(B) \]
(For more detail, see appendix A12.2).
So the iscr of an ARMA \((p,q)\) process (or ARMA \((p,d,q)\) process) is
just the acr of an ARMA \((q,p)\) (or ARMA \((q,d,p)\)) process:
Thus for an AP(p) process \( \{x_t\} \), the iacr is has cut-off after lag \( p \) (i.e., the iacr is just the same as the acrf of an MA(p) process).

So

\[
I(k) = \begin{cases} 
1 & k = 0 \\
0 & |k| > p \\
\sum_{j=L}^{P} \sum_{j=1}^{P-k} \alpha_{j} & \text{otherwise}
\end{cases}
\]  

(7.21)

where the \( \alpha_{j} \) are the coefficients in an MA(p) process by the definition of the acrf of an MA(p) process - see (6.9) in section 6.2 and substitute for \( \rho \) (see appendix A11).

Similarly, for an MA(q) process, the iacr is just the same as the acrf of an AR(q) process. For an ARMA (p,q) process the iacr is the same as the acrf in an ARMA (q,p) process.

(See appendix A12.2)

Cleveland (1972) claims that the iacr is superior (for identification purposes) to the pacrf, as a result of the complicated form of the pacrf.

For an MA(q) process, we obtain inverse Yule-Walker equations of the form

\[
I(k) = \sum_{j=1}^{q} I(k-j) + \cdots + I(k-q) = 0 \quad k = 1, \ldots, q
\]  

(7.22)

In appendix A12, two techniques for estimating the iacr are given. The asymptotic behaviour of the iacr's is also treated there.

[Note that as a result of the form of the iacr, an additional function, the inverse pacrf (ipacrf), may be defined in a manner analogous to the way in which we defined the pacrf (in section 6.4.)].
Thus, if the iacr{f} and ipacr{f} are estimated, we may also determine \( p \) and \( q \), in the ARMA \((p,q)\) process, from these two functions. If the iacr{f} truncates after lag \( p \), this would indicate that \( X_t \) is an AR\((p)\) process. If the ipacr{f} truncates after lag \( q \), then \( X_t \) would seem to be an MA\((q)\) process. Similarly if neither the iacr{f}, nor the ipacr{f}, truncate, then this indicates an ARMA \((p,q)\) process \( (p,q \neq 0) \). Then analogous to the acrf and pacrf, the number of anomalous terms in the iacr{f} and ipacr{f} are \( p-q \) and \( q-p \) respectively (Hipel et al. (1977)).

7.3 PHASE THREE: ESTIMATION OF MODEL PARAMETERS

Having tentatively identified a model (i.e. \( p, d \) and \( q \) in the ARMA \((p,d,q)\) process) for the data, we now need to calculate efficient estimates of the parameters in the model

\[
\mathbb{Z}(B)\mathbb{X} = \mathbb{E}(B)\mathbb{Y}
\]

where \( \mathbb{X} \) is a zero-mean stationary process (and if \( d \) the degree of differencing, is greater than zero, then \( \mathbb{X}_t = \mathbb{Y}_t \)).

In chapter six, we saw how to obtain estimates in an AR\((p)\) process - by using the Yule-Walker equations. Techniques were also proposed for MA and ARMA processes (appendices 9 to 11). In this section, the estimation procedure will be tackled more formally.

If our realization of the stationary process \( \mathbb{X}_t \) is \( x_1, x_2, \ldots, x_N \), then it may be shown that the unconditional log-likelihood function of the process is given by

\[
\mathbb{L} = \sum_{t=1}^{N} \log f(x_t)
\]

For computational convenience
$$L^* = L^*(\hat{\theta}, \hat{\varphi}, \tau) = f(\hat{\theta}, \hat{\varphi}) - N \log \sigma^2 - S(\hat{\theta}, \hat{\varphi})/2$$  \hspace{1cm} (7.23)$$

(see Box and Jenkins (1976) pg. 213)

where

$$S(\hat{\theta}, \hat{\varphi}) = \sum_{t=0}^{N} a_t^2$$  \hspace{1cm} (7.24)$$

where the \( a_t \)'s are calculated recursively from \( \hat{\theta}, \hat{\varphi} \) and \( x \)

and

$$\hat{\theta}' = (\hat{\theta}_1, \ldots, \hat{\theta}_p)$$  \( f(\hat{\theta}, \hat{\varphi}) \) a function of \( \hat{\theta} \) and \( \hat{\varphi} \)

$$\hat{\varphi}' = (\hat{\varphi}_1, \ldots, \hat{\varphi}_q)$$

$$\hat{x}' = (x_1, x_2, \ldots, x_N)$$

with \( (a_t^2, \hat{x}) = E(a_t^2 | \hat{\theta}, \hat{\varphi}, x) \) (i.e. the expectation of \( a_t^2 \)

conditional on \( \hat{\theta}, \hat{\varphi} \) and \( x \))

\( S(\hat{\theta}, \hat{\varphi}) \) is called the unconditional sum of squares.

Usually \( f(\hat{\theta}, \hat{\varphi}) \) in (7.23) is only of importance if \( N \) is small

(Box and Jenkins (1976), pg. 213) while if \( N \) is large then \( L^* \) is dominated by \( S(\hat{\theta}, \hat{\varphi}) \). If we find \( \text{LSE}^\theta \) of the parameters from

\( S(\hat{\theta}, \hat{\varphi}) \), then (if \( N \) is large) these estimates should be approximatively equal to the maximum likelihood estimates (MLE\( ^\theta \)) from \( L^* \).

However, by the form of (7.24), we need to calculate

$$a_t^2 | \hat{\theta}, \hat{\varphi}, x \) \forall t \) \hspace{1cm} (where \ from now on \ we \ denote \ \{a_t\}, \{x\})$$

by \( \hat{a}_t \) i.e. the conditional expectation of the white noise variables

(residuals).

7.3.1 CALCULATING THE UNCONDITIONAL SUM OF SQUARES (USS)

In the calculation of the USS, the \( a_t^2 \)'s are computed recursively

by taking the conditional expectations in

$$a_t = \hat{\sigma}(B)x_t + \hat{\varphi}(B)a_t \hspace{1cm} (t \leq N)$$  \hspace{1cm} (7.25)$$
where \( \varphi(B) \) is as before but

\[
\varphi^*(B) = \theta_0 B + \ldots + \theta_p B^p
\]

(i.e. \( \varphi^*(B) = 1 - \varphi(B) \)).

By the form of (7.24), i.e. the USS, we need \( \{x_t\} \) for \( -\infty < t < N \) and so obviously values (or estimates) for \( x_0, x_{-1}, x_{-2}, \ldots \) (i.e. "backforecasts").

Since \( \varphi(B)x_0 = \varphi(B)a_0 + \epsilon_t \) then it is equally possible that the data could be generated by the model

\[
\psi(F)x_t = \theta(\psi) \epsilon_t
\]

(7.26)

\( F = \) forward shift operator

\( \{\epsilon_t\} = \) white noise process

\[ \text{Heuristic proof: If } \varphi(B)x_t = \varphi(B) a_t + \epsilon_t \]

and the zeroes of \( \psi(B) \) and \( \varphi(B) \) lie outside the unit circle then we may write the model as

\[
\sum_{i=1}^{\infty} (1 - \varphi_i B)x_t = \sum_{i=1}^{\infty} (1 - \psi_i B)a_t
\]

where \( \psi_i \) and \( \varphi_i \) are the roots of \( \psi(B) = 0 \) and \( \varphi(B) = 0 \) resp.

Now if \( \chi_0 \) has acvlgf \( \chi(B) \), then

\[
\chi(B) = \sum_{i=1}^{\infty} (1 - \varphi_i B)^{-1}(1 - \psi_i F)^{-1}, \quad \sum_{i=1}^{\infty} (1 - \varphi_i B)(1 - \psi_i F)
\]

(see section 7.2.1)

But we may write (by multiplying out)

\[
(1 - \varphi_i B)(1 - \psi_i F) = \sum_{j=1}^{\infty} (1 - \varphi_j B)(1 - \psi_j F)
\]

so any of the 'models'

\[
\sum_{i=1}^{\infty} (1 - \varphi_i B)x_t = \sum_{j=1}^{\infty} (1 - \psi_j F)x_t
\]
can have the same acvgf if \( k \) is appropriately chosen. But since all the \( c_j^k \) and \( e_j^k \) lie inside the unit circle, the acvgf is unique.

Similarly, \( \zeta(B) \) is unchanged if \((1-\cdot B)\) is replaced by \((1-\cdot F)\) or \((1-\cdot B)\) by \((1-\cdot F)\) and so all 'models' of the form

\[
P \sum_{j=1}^{p} (1-\cdot B_j^T)X_j = \sum_{j=1}^{q} (1-\cdot B_j^T)a_j \quad (B^{-1} = F)
\]

have the same covariance structure.

(7.26) is referred to as the forward form of the process and is used to generate the back forecasts \( x_0, x_{-1}, \ldots \). (7.25) is then used to generate the \( a_t^k \).

More formally, letting \( \mathbf{v}_t = E \mathbf{v}_{t+2, 2, \ldots} \):

(i) generate \( \mathbf{v}_t \), \( t = N - p, \ldots, 1 \) and set \( \{e_j\} = 0 \) if \( j \leq 0 \)

(ii) the \( \{e_j\} \) in (i) are generated by using

\[
\mathbf{v}_t^* = \Phi(F)\mathbf{x}_t + \zeta^*(F)(e_{t+1})
\]

\[
\zeta^*(F) = 1 - \Phi(F), \quad t = N - p, N - p - 1, \ldots, 1
\]

and \( \{e_j\} = 0 \) if \( t < N - p \)

(since \( E(e_j) = 0 \) \( \forall t \))

(iii) generate the back forecasts of \( \mathbf{v}_t \) by using

\[
\mathbf{x}_t^* = \Phi(F)(e_{t+1}) - \zeta^*(F)\mathbf{x}_t
\]

(where \( \zeta^*(F) = \ldots + \lambda_F^p \))

\( t = 0, -1, -2, \ldots \)

(iv) do (iii) until the back forecasts become negligible (i.e. zero) - which occurs at \( R \) say (\( R \) a negative integer)

(v) define \( a_t^k = 0 \) if \( t < R \)

(since \( E(a_t^k) = 0 \) \( \forall t \))
(vi) use
\[ a_t = \phi(B)x_t + \theta(B)\epsilon_t \]
to generate the \( a_t \) for \( t = 1, R+1, \ldots, -1, 0, 1, 2, \ldots, N \).

(vii) \( S(\hat{\xi}, \hat{\beta}) \) may now be calculated.

(viii) if required, the whole procedure may be performed
iteratively, starting off each successive iteration by
using \( a_N \) to calculate the forward forecasts of the
\( x_t \) using
\[ x_t = \phi(B)x_t + \theta(B)\epsilon_t \]
the forward forecasts of \( x_t \) may then be used in
\[ \epsilon_t = \phi(B)x_t + \theta(B)\epsilon_t \]
to obtain new back forecasts

However, we always need \( \hat{\xi} \) and \( \hat{\beta} \) to calculate \( S(\xi, \beta) \) and the
reason we want \( S(\xi, \beta) \) is to obtain \( \hat{\xi} \) and \( \hat{\beta} \). Obviously, a grid-
search may be performed to find the \( \hat{\xi} \) and \( \hat{\beta} \) to minimize \( S(\xi, \beta) \)
although usually the techniques described in chapter 6 are used.

7.3.2 VARIANCES AND COVARIANCES OF Nile

Box and Jenkins (1976, pg. 226) state that if \( x_t \) has an ARMA \((p, q)\) representation, then over the relevant region of the parameter
space, the log-likelihood function, \( L^* \) (as defined in (7.23)),
will be approximately quadratic in the elements of \( \hat{\xi} \) and \( \hat{\beta} \). Thus
\[ L^* = L^*(\hat{\xi}, \hat{\beta}) \]
\[ L^*(\xi, \beta) \]
say
\[ L^*(\xi, \beta) = \frac{1}{2} \sum_{i=1}^{k} \sum_{j=1}^{k} \left( \frac{\epsilon_i}{\epsilon_j} \right) \]
(7.27)

where \( k = p + q \).
and \( l_{ij} = \frac{2L(\theta, a)}{a} \) (7.28)

are (approximately) constant.

Since

\[ L^* = f(\theta, \mathbf{a}) - N \log a - \frac{S(\theta, \mathbf{a})}{2a} \]

(7.28a)

(by (7.23))

then for large \( N \), \( f(\theta, \mathbf{a}) \) can be ignored and so \( L^* \) is quadratic in \( \theta \) if \( S(\theta) \) is quadratic in \( \theta \).

Define

\[ \| - E(l_{ij}) \| = 1(j) \]

(7.29)

\[ = k \text{-} k \text{ 'information' matrix( and expectation is over } \mathbf{x} \).} \]

If \( \mathbf{a} \) is given, then, from asymptotic likelihood theory

\[ \mathbf{Z} = (-E(l_{ij}))^{-1} \]

(7.30)

(i.e. the variance-covariance matrix)

Defining

\[ S_{ij} = \frac{2L(\theta, a)}{a} \quad \forall i, j \] (7.31)

then

\[ l_{ij} = S_{ij}/2a \quad \forall i, j \] (7.32)

and

\[ L(\mathbf{x}) = 2\sigma_d \mathbf{S}_{ij}^{-1} \] (7.23)

(if we approximate \( l_{ij} \) and hence \( S_{ij} \) by their observed values)

Box and Jenkins (1976, appendices A7.4 and 17.5) have shown that...
by differentiating (7.28a) w.r.t. \( \theta \) \nabla
\[
\mathbf{Cov}(\theta_a, \theta_b) = 0
\]
\[
\mathbf{Cov}(\theta_i, \theta_j) = 2c^2 \mathbf{S}^{ij}
\]
where \( (\mathbf{S}^{ij}) = (\mathbf{S}^{ij})^{-1} \)

(7.36) is derived directly from (7.30) to (7.32).

It may also be shown that if \( S(\theta) \) is 'reasonably' quadratic in the model parameters, then a \((1-\alpha)\) confidence region is bounded by the contour on the SS surface, for which

\[
S(\hat{\theta}) \leq S(\hat{\theta})^\frac{1}{2} + \frac{k}{N} \left(1 - \frac{2}{k+1}\right)
\]

where \( k = p + q \)

(see, for instance, Box and Jenkins (1976) pg. 228 or use general linear least squares theory)

7.3.3 NONLINEAR ESTIMATION OF \( \hat{\theta}, \hat{\theta}_0 \) AND \( \hat{\theta}_a \)

For most cases, the MLE\(^2\) of \( \hat{\theta}_0 \) and \( \hat{\theta}_a \) are closely approximated by the LSE which minimize

\[
S(\hat{\theta}_a, \hat{\theta}_0) = \sum_{i=1}^{N} a_t^2
\]

(which may be approximated by

\[
\sum_{t=R}^{N} \left| a_t \right|^2 = -2(\mathbf{S}^{ij})^{-1}
\]

What we really need to calculate in (7.38) is

\[
\hat{\theta}_a^2 = \sum_{t=R}^{N} a_t^2
\]

(7.39)
where $\theta_i$ is one of the $\psi_i$ or $\phi_i$. Numerical estimates of (7.39) may be obtained by using any of the several nonlinear estimation techniques available. (Several optimization techniques which do not involve finding derivatives in the sum of squares, are also available.) Some of the more extensively applied algorithms include Gauss linearization (Draper and Smith, 1966, chapter 10), steepest descent (Fletcher and Powell, 1963), Marquardt's algorithm (Marquardt, 1963) and the method of conjugate directions (Powell, 1964a, 1964b).

7.4 PHASE FOUR : CHECKING THE "OF THE MODEL AND DETERMINING THE BEST MODEL

Especially in the case where $X_t$ is an ARMA process (with $p$ and $q > 0$), we may formulate several models (due to the difficulty of deciding exactly how many terms in the acrf, pacrf, iacrf and ipacrf are anomalous). Obviously, when we have several models we would like some technique which may ascertain the 'best' model. We would also like to 'test' whether the residuals from the fitted model are sufficiently like a white noise process (and hence we may stop modelling).

7.4.1 MODEL INADEQUACY

Suppose we model $X_t$ by

$$\phi(B)x_t = \theta(B)a_t$$

then

$$a_t = \psi(B)\phi(B)x_t \quad \forall t$$

and so the residuals of the model are given by
\[ a_t = \phi(B)x_t \]  

(7.40)

It is possible to show that

\[ a_t = a_t^* + O\left(\frac{1}{n}\right) \]  

(7.41)

If the model is adequate (Box and Jenkins, 1976, pg. 289) so as $N$ increases, the estimated residuals become more and more like white noise.

Appendix A13) has shown that if $\phi$ and $\theta$ are 'known', then the estimated acf's of the $a_t^*$ are uncorrelated and independent and are approximately normally distributed as \(N(0, \frac{1}{N})\).

If some pattern occurs in the residual acf, this probably indicates model inadequacy.

\[ r_{a,a} = \frac{1}{N}N\left(0, \frac{2}{N}\right) \]  

Appendix A13)

\[ r_{a,a} = N(0,1) \]  

and hence

\[ \sum_{k=L}^{\infty} r_{a,a}^2 \]

Box and Jenkins (1976, pg. 290) have developed a test they term the portmanteau lack of fit test, and here they calculate

\[ Q = N \frac{1}{L-p-q} \sum_{t=1}^{L-p-q} a_t^2 \]  

(7.42)

If the model is 'appropriate' (i.e. the residuals are pure white noise) however Davies et al (1977) have shown that a test based on $Q$ is unreliable. See also Ljung and Box (1978).
Ljung and Box (1978) have offered a variation on (7.12) namely

\[ Q' = \sum_{i=1}^{N-1} \frac{1}{N-i} r_{i}^2, \quad (7.43) \]

and claim this is superior to \( Q \).

Several other techniques exist for testing the 'whiteness' of the residuals.

For instance, define

\[ r_{a}^2 = (r'_{a,1}, \ldots, r'_{a,n}), \]

Let \( k(z) \) and \( k(z) \) be the coefficients of \( B^k \) in the Maclaurin series expansion of \((\gamma(1))^{-1}\) and \((\gamma(9))^{-1}\) (resp.) in powers of \( B \) (Also see appendix A13). Then it can be shown, for large \( N \), that

\[ r_{a}^2 \sim \frac{1}{N} U \]

where

\[ U = I_{L} - X \quad \text{identity matrix} \]

\[ I = X^TX \]

\[ X = [r'_{1-j}, r'_{1-j}] \]

(where \( r'_{1-j} \) and \( r'_{1-j} \) are the \( 1 \times 1 \) entries in the two partitions of \( X \) - these partitions have dimensions \( L \times p \) and resp. and so \( X \) has dimension \( L \times (p+q) \))

A 'good' diagnostic check of the residuals is to plot the residual acrf along with asymptotic significance levels for the residuals.

See, for example, Box and Pierce (1970).
acrF (obtained from the diagonal entries of the matrix $\frac{1}{n} U$, see Hipel et al. (1977)). If some of the residual acrF are significantly different from zero, this implies that the model is inadequate.

The $a_t$ may also be checked for normality. Normally distributed data should possess no significant skewness, and kurtosis equal to (approximately) three. In Appendix A1, ARMA processes with nonnormal residuals are considered. If the residuals possess significant skewness and kurtosis, a transformation of the original data may remove this and thus make the residuals more normal.

Alternatively, the cumulative periodogram of the residuals may be calculated.

$$I^*(w_j) = \frac{1}{2} \left( \sum_{j=0}^{\left\lfloor \frac{N}{2} \right\rfloor} c_{a,j} \cos(tw_j) \right)$$

$$j = 0, \ldots, \left\lfloor \frac{N}{2} \right\rfloor \quad w_j = 2^{-j}/N$$

$h(w)$ an estimate of the spectrum (see section 4.1)

$\{c_{a,j}\}_{k}$ = estimate of the acv(at lag k) of the residuals).

If the residuals are pure white noise then

$$h(w) = \frac{1}{2\pi} 2^{-j/2}$$

(since $h(w) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{a}(t) \cos(tw) \, dt$ by definition

but $\hat{a}(t) = 0$ if $|t| > 0$)

The cumulative spectrum, $H(w)$, may be defined by

$$H(w_j) = \int_{0}^{\left\lfloor \frac{N}{2} \right\rfloor} h(w) \, dw$$

This is not the definition of the true cumulative spectrum - that is defined by

$$\int_{-\infty}^{\left\lfloor \frac{N}{2} \right\rfloor} h(w) \, dw$$
acr£ (obtained from the diagonal entries of the matrix \( \frac{1}{N} \mathbf{U} \), see Hipel et al. (1977)). If some of the residual acrs are significantly different from zero, this implies that the model is inadequate.

The \( \tilde{a}_k \) may also be checked for normality. Normally distributed data should possess no significant skewness, and kurtosis equal to (approximately) three. In appendix A1.4, ARMA processes with nonnormal residuals are considered. If the residuals possess significant skewness and kurtosis, a transformation of the original data may remove this and thus make the residuals more normal.

Alternatively, the cumulative periodogram of the residuals may be calculated:

\[
L^s(w_j) = \frac{1}{\pi} \sum_{k=-N}^{N} \tilde{a}_k \cos(kw_j) \\
\text{where } j = 0, \ldots, \lfloor \frac{N}{2} \rfloor \quad w_j = 2\pi j/N
\]

\( h(w) \) an estimate of the spectrum (see section 4.1)

\( \tilde{a}_k \) = estimate of the acv(at lag k) of the residuals.

If the residuals are pure white noise then

\[
h(w) = \frac{2}{\pi} \frac{1}{a} \frac{1}{t}^2 \cos(t) \\
\text{(since } h(w) = \frac{1}{2\pi} \int_{-\infty}^{\infty} a(t) \cos(tw) \text{ by definition)}
\]

but \( a(t) = 0 \) if \( |t| > 0 \)

The cumulative spectrum, \( H(w) \), may be defined by

\[
H(w_j) = \int_0^{w_j} h(w) \, dw \quad 0 < w_j < \pi
\]

This is not the definition of the true cumulative spectrum — that is defined by \( \int_0^{\pi} h(w) \, dw \)
\[ H(w) = \frac{a^2}{2\pi} \int_0^w \frac{u^2}{2\pi} du \]

and

\[ H(\pi) = \frac{a^2}{2} \]

thus \( H(w) \) is a linear function of \( w \) over (0,\( \pi \)) (if \( \{a_n\} \) is a white noise process).

So define the cumulative periodogram by

\[ CI(w) = \sum_{i=0}^{j} I_i^*(w) \]

and then use some goodness of fit test or nonparametric procedure.

### 7.4.2 SELECTING THE 'BEST' MODEL

As mentioned earlier, it may happen that we have several models for the data, and wish to choose the 'best' one. Several techniques are available for assessing this 'bestness'.

Akaike (1970) defined a criterion for assessing the best model by

\[
\text{AIC} = \text{Akaike's information criterion} = -2\ell + 2K \quad (\text{maximum likelihood function of the process}) + 2(\text{no. of parameters in the model})
\]

or equivalently (for \( N \) large and hence \( f(\cdot) \) negligible - see pg.134)

\[
\text{AIC} = N \frac{q^2 + 2K}{2} \quad K = p - q - 1
\]

\[ q^2 = \frac{S(\cdot)}{N} \quad (\text{see pg. 139}) \]
since
\[ L^* (\text{ML function}) = L^* = - \frac{N}{2} \ln \gamma_a^2 - \frac{1}{2} \gamma_a^2 \chi^2 (\text{for large } N) \]

and hence \( f(\gamma_a^2) \) negligible - see pg. 138)

where \( \gamma_a^2 = (\gamma_1, \ldots, \gamma_p, \gamma_q, \ldots, \gamma_q) \).

and \( L^* \) maximized w.r.t. \( \gamma_a^2 \) and \( \gamma_a^2 \) gives

\[ \gamma_a^2 = \frac{1}{N} \chi^2 (\gamma) \]

and the maximum of \( L^* \) is

\[ L^* = - \frac{N}{2} + \frac{1}{2} \gamma_a^2 - \frac{N}{2} \chi^2 \]

(and the second term can be ignored since it is independent of \( \gamma_a^2 \) and \( \gamma_a^2 \)).

The model with the minimum AIC is defined to be 'best'.

Akaike (1970) also defined, for AR processes, a criterion for determining the 'best' model.

Define

\[ \text{FPE} = \text{final prediction error} = \frac{N-k}{N-k} \gamma_a^2 \]

where \( k = p \) and \( \gamma_a^2 \) is the WLE of \( \gamma_a^2 \).

The AR process with minimum FPE is the best fitting model.

[It may be shown that

\[ \text{AIC} = N \cdot \text{FPE} \]

More recently, Akaike (1979), has developed a new criterion for order determination in ARMA processes]
\[ \text{BIC} = N \left( \frac{\hat{\sigma}^2}{N} - (N-k) \left( 1 - \frac{k}{N} \right) + k \ln N + k \ln \left( \frac{1}{\hat{\sigma}^2} \right) \right) \]

where \( \frac{\hat{\sigma}^2}{N} \) is the raw sample variance of the observations

\[ k = p + q \]

Parzen (1974), has also developed a technique for choosing the best fitting AR process using the CAT (Criterion for AR transfer functions) quantity defined by

\[ \text{CAT}(p) = \begin{cases} \frac{p}{\hat{\sigma}^2} & \text{if } p \leq 1 \text{ or } j = 0 \\ \frac{1}{\hat{\sigma}^2} & \text{if } p > 1 \text{ or } j > 0 \end{cases} \]

where \( \hat{\sigma}^2_j \) is an (unbiased) estimate of the residual variance, \( \sigma^2_a \), when an AR(j) model is fitted. Choose the best fitting AR process when CAT is minimized.

A technique developed by McClave (1975, 1978, 1978a) for choosing the 'best' AR or MA model is described in appendix A15. This technique usually uses one of the above criteria (i.e. AIC, FPE, BIC or CAT). This technique is mentioned here instead of in section 7.2, since it involves fitting several models and then choosing the best.

Usually, if the model is deemed inadequate, either the residuals themselves may be studied further or (if this is not possible) it may be necessary to transform the data (and hence start all over again). A class of transformations is presented in appendix A16.
7.5 PHASE FIVE: FORECASTING

Having deemed the model (model?) to be satisfactory, we may wish to forecast estimates of future values. This is not particularly difficult, due to the form of the Box-Jenkins models, and is discussed more fully in appendix A17.

7.6 SEASONAL BOX-JENKINS MODELS

So far, the concept of a seasonal Box-Jenkins model has not been discussed since we have considered our data to be deseasonalized (by using periodogram or harmonic analysis). However it may so happen that either

(a) we neglected to remove some periodic component
or (b) we do not wish to use harmonic analysis.

In case (a), any periodicity in the data, which is not modelled, will probably be picked up in the residual acrf (or it may even be apparent in the residuals themselves). In (b), we must either deseasonalize the data using some other technique, or allow for the seasonal components by modelling them.

Let us assume the data contain some seasonal components and we wish to model them by somehow modifying the B-J techniques. Suppose the periodic behaviour has period $S$ - i.e. similarities in the data appear every $S$ basic time intervals.

Since observations $S$ intervals apart are similar, it seems reasonable (assuming stationarity) that

$$
\theta_{S} = \theta_{S+1} = \theta_{S+2} = \ldots
$$
plays some role in the model. It is also possible that
\[ \nabla_S x_t = (1 - B^S)x_t \]

or even \( x_t - x_{t-S} \)

(Note that \((1 - B^S)\) has \(S\) zeroes \(e^{2\pi jk/S}, k = 0, \ldots, S-1\) evenly spaced on the unit circle.)

If the data are monthly say, then the two important time intervals correspond to months and years i.e. we expect relationships between successive months as well as relationships between months a year apart.

A model to link December say, to observations in previous

Decembers, may be
\[ \nabla(B^S - D) S^x_t = \nabla(B^S)e_t \]

\( S = \text{period (in our case 12)} \)

\( D = \text{degree of seasonal differencing} \)

\( \nabla(B^S) = \text{polynomial in } B^S \text{ of degree } P_i \)

\( \nabla(B^S) = \text{polynomial in } B^S \text{ of degree } P_j \)

and \( \nabla(B^S) \) and \( \nabla(B^S) \) satisfy stationarity and invertibility conditions.

The \( e_t \) will not usually be uncorrelated (i.e. the observation for December, while related to the previous December, may also bear some relationship to November, October etc). To take this into account, we model
\[ \nabla(B^d) e_t = \nabla(B^d) a_t \]

where
polynomials in $B$ just as before.

So our overall model is

$$(3): (B^S)^{d_1} (B^S)^{D_1} = (B^S)^{S^q_1} a_t$$  \hspace{1cm} (7.44)

- this is termed a $(p,d,q) \cdot (P_3,D,Q_3)_S$ B-J model

If the data contain 2 or more seasonal components then we may model each component as in (7.44).

Our first job now is to determine $d_1, D_1, p, q, P_3$ and $Q_3$.

Firstly, for $d$ and $D$, just apply $(1-B)$ and $(1-B^3)$ until the sample acr's of the differenced series die out quickly at high lags.

Hill and Woodworth (1980) have suggested finding

$$a_t = (4,D,D)_1 = (4,D,D)_S$$

Once the acrf of the differenced series dies out quickly enough for lags 1,...,$S$ and also at multiples of $S$, we may then attempt to estimate $p$, $q$, $P_3$, and $Q_3$.

A summary of the properties of seasonal models is given below and this enables us to gain an idea about $p$, $q$, $P_3$, and $Q_3$. (For a fuller account see Box and Jenkins (1976), Chapter 9).

7.6.1 THE ACRF

(1) If the process is $(0,q) \cdot (C,Q_3)_S$, then $a_t$ truncates after $q = 3Q_3$.
(ii) If $r_1$ attenuates at lags which are multiples of $S$, then this implies the presence of a seasonal AR component; if the acrf fails to truncate at other lags, this may imply a nonseasonal AR component.

7.6.2 THE PACRF

(i) If the process is $(p,0) \times (P_S,0)$, then $r_1$ truncates after $p + SP_S$

(ii) If $r_1$ damps out at lags which are multiples of $S$, this implies the presence of a seasonal MA component; the failure of the pacrf to truncate at other lags may imply a nonseasonal MA component.

7.6.4 THE IPACRF

(i) If the process is $(0,q) \times (0,Q_S)$, then $r_1$ truncates after $q + SQ_S$

(ii) If $r_1$ decays at lags which are multiples of $S$, then this implies the presence of a seasonal AR component. Failure of the ipacrf to truncate at other lags implies a nonseasonal AR component.
[For further details, see Box and Jenkins (1976) and Hipel et al (1977).]

Having estimated $p,q,P$, and $Q$, parameter estimation follows in a manner similar to the nonseasonal BJ models, and hence forecasts. Diagnostic checks on the fit of the model are also similar to those of the nonseasonal models.
CHAPTER 8: NONLINEAR MODELLING AND MISCELLANEOUS NOTES

In the previous two chapters, a special branch of time-series models has been considered — namely linear time-series models. In these, the (present) observation $x_t$ is considered as a linear combination of past values of $x_t$ as well as a linear function of some noise variables $a_i$. This assumption of linearity can be very restrictive and it also seems reasonable to consider nonlinear combinations of the observations and noise variables:

$$x_t = a_1 + a_2 x_{t-1} + a_3 x_{t-2} + \cdots + a_k x_{t-k}$$

recently a class of nonlinear time-series models called near models has been proposed. These models seem to offer more extensive possibilities. A brief description of these models and their parameter estimates are given below.

**OUR TIME-SERIES MODELS**

Near models are of the form:

$$\sum_{i=1}^{p} \sum_{j=1}^{q} \alpha_{i,j} x_{t-i} + \beta_{i,j} a_{t-j} = \sum_{k=1}^{m} \gamma_{k} x_{t-k} + \delta_{k} a_{t-k},$$

where $x_t$ is a mean stationary process and $\{a_t\}$ is a white noise series (and $\gamma = 0$).

The representation (8.1) may be written in the abbreviated form:

$$BL(p,q,m,k)$$

where $i = 0, 1, \ldots, k$ and $j = 0, 1, \ldots, k$.

If $k = 0$, then $BL(p,q,0,0) = \text{ARMA}(p,q)$.
The bilinear models with the 'easiest' theory are those of the form

\[ \text{BL}(p,0,p,q) \] (due to the form of the model)

\[ x_t + \delta_0 \sum_{j=1}^{p} \delta_j x_{t-j} + \sum_{i=1}^{q} \gamma_i x_{t-i-j} = a_t \] (8.3)

(not necessarily 1).

Assume the \( a_t \) in (8.3) are independent and \( \sim N(0,\sigma_a^2) \). Also assume (8.3) is an 'invertible' model (i.e. if \( x_t \) satisfies

\[ x_t = \text{[function of]} (x_{t-j},a_{t-j}; j=1,\ldots,p) + a_t \]

and \( \hat{a}_t \) are estimates of \( a_t \) then

\[ \lim_{t \to \infty} E[\hat{a}_t - a_t] = 0 \].

Suppose we have a realization \( x_1, x_2, \ldots, x_N \). Define

\[ m = \max\{p,q\} + 1 \]

then the joint distribution of

\[ a' = (a_m, a_{m-1}, \ldots, a_N) \]

is

\[ g(a) = \frac{1}{2^{\frac{N-m+1}{2}}} \exp\left(-\frac{1}{2} \sum_{t=m}^{N} \frac{a_t^2}{\sigma_a^2}\right) \] (8.4)

(since the \( a_t \) are \( \sim N(0,\sigma_a^2) \) independently).

Now the likelihood function of \( x' = (x_m, \ldots, x_N) \) is the same as the joint pdf of \( a \) since the Jacobian of the transformation from \( a \) to \( x \) is 1. Thus maximizing the likelihood function, w.r.t. the model parameters, is equivalent to minimizing

\[ S(\hat{a}) = \sum_{t=m}^{N} \frac{a_t^2}{\sigma_a^2} \] (8.5)
where \( \tilde{y} = (\tilde{y}_1, \ldots, \tilde{y}_s) \), \( \tilde{y} = (y_1, \ldots, y_q) \) say \( R=q=p=q=1 \)

So

\[
\frac{\partial \tilde{y}(\tilde{z})}{\partial \tilde{z}_k} = 2\tilde{y}_k \frac{\partial \tilde{a}_k}{\partial \tilde{z}_k}, \quad k = 1, \ldots, s
\]

and

\[
\frac{\partial^2 \tilde{y}(\tilde{z})}{\partial \tilde{z}_k \partial \tilde{z}_l} = 2\tilde{y}_k \frac{\partial^2 \tilde{a}_k}{\partial \tilde{z}_k \partial \tilde{z}_l} - 2\tilde{y}_l \frac{\partial^2 \tilde{a}_l}{\partial \tilde{z}_k \partial \tilde{z}_l}
\]

These partial derivatives satisfy

\( (1) \)

\[
\frac{\partial a_{i,j}}{\partial k} = \sum_{k=1}^{q} \left( \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \right) \frac{\partial z_k}{\partial k} - \sum_{k=1}^{q} \frac{\partial a_{i,k}}{\partial k} \frac{\partial z_l}{\partial l} - \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \frac{\partial z_k}{\partial k} \frac{\partial z_l}{\partial l} = 0
\]

\( i = 1, \ldots, q \quad j = 1, \ldots, q \)

\( (2) \)

\[
\frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} = \sum_{k=1}^{q} \left( \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \right) \frac{\partial z_k}{\partial k} - \sum_{k=1}^{q} \frac{\partial a_{i,k}}{\partial k} \frac{\partial z_l}{\partial l} - \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \frac{\partial z_k}{\partial k} \frac{\partial z_l}{\partial l} = 0
\]

\( i = 1, \ldots, q \quad j = 1, \ldots, q \)

\( (3) \)

\[
\frac{\partial^3 a_{i,j}}{\partial z_k^3} = \sum_{k=1}^{q} \left( \frac{\partial^3 a_{i,j}}{\partial z_k^3} \right) \frac{\partial z_k}{\partial k} - \sum_{k=1}^{q} \frac{\partial a_{i,k}}{\partial k} \frac{\partial z_l}{\partial l} - \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \frac{\partial z_k}{\partial k} \frac{\partial z_l}{\partial l} = 0
\]

\( i = 1, \ldots, q \quad j = 1, \ldots, q \)

\( (4) \)

\[
\frac{\partial a_{i,j}}{\partial z_k} = \sum_{k=1}^{q} \left( \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \right) \frac{\partial z_k}{\partial k} - \sum_{k=1}^{q} \frac{\partial a_{i,k}}{\partial k} \frac{\partial z_l}{\partial l} - \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \frac{\partial z_k}{\partial k} \frac{\partial z_l}{\partial l} = 0
\]

\( i = 1, \ldots, q \quad j = 1, \ldots, q \)

\( (5) \)

\[
\frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} = \sum_{k=1}^{q} \left( \frac{\partial^3 a_{i,j}}{\partial z_k^3} \right) \frac{\partial z_k}{\partial k} - \sum_{k=1}^{q} \frac{\partial a_{i,k}}{\partial k} \frac{\partial z_l}{\partial l} - \frac{\partial^2 a_{i,j}}{\partial z_k \partial z_l} \frac{\partial z_k}{\partial k} \frac{\partial z_l}{\partial l} = 0
\]

\( i = 1, \ldots, q \quad j = 1, \ldots, q \)
i, r = 1, ..., p
j, s = 1, ..., q

(see Subba Rao (1981)).

Now assuming \( a_t \equiv 0 \) (t = 1, ..., m) and
\[
\frac{\partial^2 a_t}{\partial \lambda^2} = 0, \quad \frac{\partial^2 a_t}{\partial A^2} = 0
\]  

\( t = 1, ..., m \)

then together with (8.9), this implies the second-order derivatives
w.r.t. \( \lambda \) (i = 2, ..., p) are zero.

Define
\[
S'(\lambda) = \left( \begin{array}{c}
\frac{\partial S(\lambda)}{\partial \lambda_1} \\
\vdots \\
\frac{\partial S(\lambda)}{\partial \lambda_p}
\end{array} \right)
\]

and
\[
S''(\lambda) = \left[ \begin{array}{c}
\frac{\partial^2 S(\lambda)}{\partial \lambda_1^2} \\
\vdots \\
\frac{\partial^2 S(\lambda)}{\partial \lambda_p^2}
\end{array} \right]_{R \times R}
\]

(i.e. a matrix of second-order derivatives) then expanding \( S'(\lambda) \) in a Taylor series near \( \lambda = \lambda_0 \)
gives
\[
S'(\lambda) \approx 0 \implies S'(\lambda) = S''(\lambda) \cdot (\lambda - \lambda_0)
\]

thus
\[
\lambda - \lambda_0 \approx S^{-1}(\lambda) \cdot S'(\lambda) \cdot (\lambda - \lambda_0)
\]

where \( S(\lambda) = (S^{-1}(\lambda))^{-1} \)

and so
\[
\frac{1}{2} (\lambda^{(k+1)} - \lambda^{(k)}) = \frac{1}{2} (\lambda^{(k)} - \lambda^{(k)}) \cdot S''(\lambda^{(k)}) \cdot (\lambda^{(k)} - \lambda^{(k)} - \lambda^{(k)})
\]

where \( \lambda^{(k)} \) is the set of estimates at the k\textsuperscript{th} iteration. This leads
to the standard Newton - Raphson iterative method of solving for

Thus letting \( L(\lambda) \) denote the likelihood function of \( \lambda = (\lambda_1, ..., \lambda_p) \)

and using the notation of Subba Rao (1981) \( \lambda \)
\[
\left( \begin{array}{c}
\frac{1}{n} \sum_{i=1}^{n} \left( x_i - \bar{x} \right)^2 \\
\frac{1}{n} \sum_{i=1}^{n} \left( y_i - \bar{y} \right)^2 
\end{array} \right) = \frac{1}{n} \left( \begin{array}{c}
\frac{1}{n} \sum_{i=1}^{n} \left( x_i \right)^2 \\
\frac{1}{n} \sum_{i=1}^{n} \left( y_i \right)^2 
\end{array} \right)
\]

\[2 \delta^2 \sum_{i=1}^{m} \delta_i^2 (s) \rightarrow e \delta^2 \mathbf{I}(1)
\]

\[
\begin{array}{c}
\frac{1}{n} \sum_{i=1}^{n} \left( x_i - \bar{x} \right)^2 \\
\frac{1}{n} \sum_{i=1}^{n} \left( y_i - \bar{y} \right)^2
\end{array}
\]

(see Subba Rao (1981)).

Subba Rao (1981) suggests fitting an AR(p) process to the data (with a constant \( \delta_0 \) included) and obtaining estimates of
\[
\mathbf{Y} = \left( y_0, \ldots, y_p \right)^T.
\]
Then use these \( \hat{\mathbf{y}} \) \((i = 0, \ldots, p)\) as initial values in the bilinear model (and set \( \mathbf{w}_1 = \mathbf{0} \)) as the initial values for \( \mathbf{h}_1 \).

Han and Subba Rao (1981) have considered subset bilinear models. These models effectively take into account the situation where parameters in the 'full' bilinear model \( \mathbf{H}(p, 0, p, q) \) may be negligibly small. They have described an algorithm for fitting a subset bilinear model.

### 4.2 Threshold Autoregressive Models

Another class of finite parameter nonlinear time series models is that known as threshold models (Tong and Lim (1980)). Here we start with a linear model for the \( x_t \), but then allow the parameters to vary according to the values of a finite number of past values.
of \( x_t \) (or some associated process \( Y_t \))

\[
\begin{align*}
\text{(1)} & \quad x_t = \begin{cases} 
\beta_0 x_{t-1} + \alpha_1 x_{t-1} + d, & \text{if } x_{t-1} \leq d \\
\gamma_0 x_{t-1} + \alpha_2 x_{t-1} + d, & \text{if } x_{t-1} > d
\end{cases}
\end{align*}
\]

where \( \alpha_1 \) and \( \alpha_2 \) are white noise processes and \( d \) is some real number.

\[
\begin{align*}
\text{(2)} & \quad x_t = \beta_1 x_{t-1} + \alpha_1 \text{ if } x_{t-1} \in R_i \\
& \text{and } R_1, \ldots, R, \text{ are given subsets of } \mathbb{R} \text{ (the real line).}
\end{align*}
\]

\[
\begin{align*}
\text{(3)} & \quad x_t = \beta_1 x_{t-1} + \cdots + \beta_p x_{t-p} + \alpha_t \text{ (if } x_{t-1}, \ldots, x_{t-p}) \in R^{(i)}
\end{align*}
\]

where \( R^{(i)} \) is a region of the Euclidean space \( \mathbb{R}^p \).

This class of models is very difficult to apply (see Gábr and Subba Rao (1981)), however they seem to give better forecasts than ARMA or subset ARMA models in most cases. Gabr and Subba Rao (1981) claim that bilinear models (and in particular subset models) give the best forecast results.

Note that these models are based on the idea of piece-wise linearization.

### 8.3 Missing Observations

Often a data set is incomplete due to missing observations. This makes it difficult to estimate the spectrum and also any kind of model. Several authors have proposed techniques for estimating the spectrum (and hence the observations) - see, for example, Bloomfield (1970, 1976).
3.1 R AND S ARRAYS

The major problem, when using the Box-Jenkins technique, is determining \( p \), \( d \) and \( q \) if \( X_t \) is an ARMA \((p,d,q)\) process. Gray, Kelly and McIntyre (1975) have obtained an effective general method for simultaneously identifying \( p \) and \( q \) by analyzing two sets of ratios of Hankel determinants (Zindeley (1981)) of sample acf's. These two sets of ratios are called \( R \) and \( S \) arrays. They have also suggested systematic procedures for identifying \( R \).

For more details see Gray, Kelly and McIntyre (1975) and Zindeley (1981).
CHAPTER 9: AN APPLICATION

In this chapter, an application of some of the techniques presented in earlier chapters is presented. The computer programs described in appendix A18 were used in this application.

9.1 THE DATA

The data consists of the 104 observations given in appendix A19 and plotted in figure 9.1. They represent weekly incoming-pasenger totals for an airline at San Juan Airport from January 1972 to February 1982. (The data set will be denoted by PASJN.)

I decided to use the first 120 observations for the process of modelling and the last 12 for forecasting purposes. The 'cut-off' point is shown in figure 9.1 (x<sub>120</sub> = 204). From this plot, there seems to be some form of periodicity of approximately 26 weeks with the stretches of data in between not too well defined.

Since our data is weekly, it perhaps should not be too surprising if the data exhibit some form of seasonality with periods 1.5, 26 or 32 weeks (i.e., quarterly, half-yearly or annually), since these are the obvious periods.

The data (or if necessary any transformation thereof) are to be modelled by

$$ s_t = \text{deterministic cycles} + \text{stochastic process} $$

where the former part may contain a trend component (i.e., a constant) and consists of any sine-cosine of fixed frequency, phase and amplitude.

Deterministic cycles (if present) are usually apparent in the
Fig. 9.1 A plot of the airline passenger data
data (i.e. a cyclic form). However, some nondeterministic cycles need not be cyclic but rather just meander around a particular frequency, phase and amplitude. Very often when some cyclicity or seasonality is apparent, a transformation of the data is made (see Chatfield (1980), pg. 13). For instance, if the data is seasonal and has escalating amplitude in the seasonal wave pattern, then a change in the variance over time, of the original data, would eventually be mirrored by heteroscedasticity in the residuals of the model fitted to the data. To rectify this situation (from the start) take natural logs of the data.

Also, the data are usually transformed if they have an asymmetrical appearance (see Campbell and Walker (1977)). Again the transformation to be used is a natural log transform (since this reduces the degree of asymmetry).

Parzen (1978) suggests a transformation without memory, or memoryless transformation, (i.e. independent of time), such as logarithm or square root if the data appear to have long tails or seem to be non-normally distributed. (Also see Parzen (1982)).

9.2 TRANSFORMING THE DATA

To ascertain whether a transformation is necessary, we shall use the technique of quantile - box plots suggested by Parzen (1978) and described in Parzen (1979).

This technique involves estimating the quantile function $Q(u)$ ($0 < u < 1$) defined by

See 'Comment' at the end of the chapter on page 214
\[ Q(u) = F^{-1}(u) \]

where \( F(x) \) is the cumulative density function (cdf) of the process from which the data is drawn.

\[ Q(u) \] is estimated by \( \tilde{F}^{-1}(u) \) where \( \tilde{F}(x) \) is the empirical distribution function (cdf) of the sample.

Once \( Q(u) \) has been plotted, \( H, K \) and \( D \) 'boxes' are superimposed on the plot and represent rectangles from the quantiles

\[
\frac{1}{4} = \frac{3}{4}, \quad \frac{1}{8} = \frac{7}{8} \quad \text{and} \quad \frac{1}{16} = \frac{15}{16}
\]

resp. (see fig. 9.2). [For more detail see Parzen (1979)].

The quantile-box plot of the data is given in figure 9.2 with associated boxes. Parzen (1979) claims that dissimilar shapes within the boxes indicates asymmetrical data. If the data appear to be symmetric it is also possible to test whether the data are nonnormal and in particular if the distribution from which they are drawn possesses long tails (see Parzen (1979) – he also provides a statistic for determining skewness).

The box plots of the \( \log_{10} \) and square root transformations are given in figures 9.3 and 9.4 resp.

Since memoryless transformations like \( \log_{10} \) or square-root do not drastically change the basic shape of the distribution of the data (if all data points are > 1), a transformation of this kind is completely optional. As a result of this, instead of using the statistics suggested by Parzen (1979), I calculated the vertical distances between successive boxes - e.g. the distances \( a, b, c, \) and \( d \) (i=1,2) given in figure 9.2 for each quantile box plot. The results are given in table 9.1.

See 'Comment' at the end of the chapter on pg. 214
Fig. 9.2 Quantile-box plot of the airline passenger data
Fig. 9.3 Quantile-box plot of $\log_{10}$ of the airline passenger data
Fig. 9.4 Quantile-box plot of the square-root of the airline passenger data.
For the data to have a symmetric appearance, $\alpha_1 = \alpha_2$ should be approximately 1. The $\alpha$ values for each plot are given in Table 9.1. Using $c$ and $d$ as criteria (since there is likely to be more variation in the tails of the data and hence the extreme quantiles), then since $\log$ gives minimum values for $c$ and $d$, I decided to make use of this transformation.

### Table 9.1: A comparison of quantile-box plots

Since this transformation step is totally optional, I am quite satisfied that the very rough procedure I have used is accurate enough for any applications we may wish to make to the data. Nevertheless, the transformation does affect the shape of the distribution and hence the appropriate model.

A plot of $\log(x(t))$ for $t=1,2,\ldots,164$ is given in figure 9.5 (and a listing of the data is given in Table A19.2, Appendix A19).

By minimum, I mean values closest to 1.

See 'Comment' at the end of the chapter on page 214.
Fig. 9.5 Plot of the transformed (log_{10}) airline passenger data
For interest's sake, figures A19.1 - A19.4 and tables A19.3 - A19.4, in appendix A19, contain information about PASSIN.

9.3 DETECTING ANY DETERMINISTIC CYCLES

The autocorrelation function of the (new) transformed data set is given in figure 9.6. Since the function is obviously not damping out at a fast rate, the data would seem to be nonstationary. This is backed up by the results given in tables A19.6 - A19.8 (appendix A19) where the time-series has been divided into the subseries lengths given and then the mean, variance and acrf of each subsection calculated.

Actually, for these tables, the first 156 (instead of 150) observations were used, in order to have segments consisting of the same number of observations (this should not affect the overall conclusion). The choice of subseries length was based upon the 'obvious' periods one may expect in weekly data (i.e. 13, 26 and 52) - any seasonality is 'more likely' to have periods corresponding to these values.

From these tables, we see that the series is at least nonstationary in its covariance structure since if the series were stationary, we would expect segments of equal length (from any point in time) to have approximately the same covariance structures. (See, for example, Gottman (1981), pg. 75).

Since the acrf of the log, data seems to be cyclic with oscillations that do not die out quickly, we may conclude that any cycles in the data must be deterministic (since nondeterministic cycles damp down to zero quickly - Gottman (1981), pg 87).

Additional checks for distinguishing deterministic from
Fig. 9.6 Autocorrelagram of the transformed data
nondeterministic cycles consist of:

(a) compute the periodogram with varying sample sizes; if the resulting plots show peaks that increase with sample size, this implies deterministic cycles (Gottman (1981), pg 197+)

and

(b) if a cycle is deterministic, then the (sample) sdf should peak sharply (approximately at one frequency); if the cycle is nondeterministic then the series repeats itself 'more or less' regularly and thus the sdf would be expected to peak across a band of frequencies.

Estimates of the sdf using the Parzen(b) window (see section 4.3.1, equation (4.25a)), with truncation points $M_1 = 0.5 \times N$ and $M_2 = 0.75 \times N$, are given in figures 9.7 and 9.8 resp. These plots seem to indicate sharp peaks thus implying deterministic cycles. (Full plots of the sample sdf are given in appendix A19 for truncation points 5%, 10%, 20%, 50% and 75% of N - see figures A19.5 - A19.10. Note how the spectrum estimate is initially smooth and as the truncation point increases tends to become 'rougher').

Now the sample sdf alone may be used to gauge at which frequencies there is 'significant' power and hence the frequencies of the deterministic cycles (and obviously the periods relating thereto). However I shall make use of the periodogram (an estimate of the sdf) to 'identify' the important frequencies (since this has been evaluated on a finer grid of frequencies).

The (natural) logarithms of the periodogram ordinates are given given in fig. 9.9. The values on the vertical axis represent frequencies (e.g. $j = 6$ corresponds to $2^{6} \times N'$ where $N'$ is the next power of 2 above 150 - the data to be modelled are $x_1 \ldots x_{150}$
Fig. 9.7 Spectrum estimate (using the Parzen (b) window (pg. 80) and truncation point 75) of the transformed (log_10) data
Fig. 9.8 Spectrum estimate (Parzen (b) window, truncation point 112) of the transformed data.
Fig. 9.9  log \(_{10}\) of the periodogram of the transformed data
- see program PGRM in appendix A18). From this plot it appears that the 'major' peaks occur at \( \omega_{5,10,20} \). In figures 9.10 and 9.11 are the periodograms with 20% and 50% tapering (see section 5.4). These 'smoothed' periodograms make the peaks clearer.

The major peak or frequency would seem to correspond to \( \omega_{10} \) with possible subsidiary peaks at \( \omega_{5} \) and \( \omega_{5} \). However from section 3.4.1, note (vii), recall that if \( x_t \) is periodic, with period \( h \), then the periodogram vanishes - i.e. is zero - at all frequencies except \( \omega = 2n/h \) and its multiples - and \( \omega_{20} \) is a multiple of \( \omega_{5} \) and \( \omega_{10} \). \( \omega_{10} \) is a multiple of \( \omega_{5} \).

However the sample sdf's (see either figs. 9.7 and 9.8 or figs. A19.5 - A19.10 in appendix 10) seem to indicate three 'distinct' peaks (not so much at \( \omega_{5} \)) thus possibly indicating a sum of three seasonal components. However, the procedure to be adopted here is that described in section 3.2 where the data will be detrended successively i.e. the major seasonal component removed from the data, the residuals then analysed for seasonality etc.

Now \( \omega_{10} = 2^{-5} \cdot 10/256 \)
\[
= 0.245436926
\]
(and the subscript 10 in \( \omega_{10} \) corresponds to a period of \( 2\pi/\omega_{10} = 26 \))
and this will serve as an initial estimate for \( \omega_{10} \) in the model
\[
x_t = \bar{x} + a_1 \cos(t\omega_{10}) + b_1 \sin(t\omega_{10}) + u_t
\]
\( u_t \) is stochastic process.

\( \omega_{10} \) is used in the program HIDP (which computes LSE's of all model parameters-see appendix A18) as an initial estimate of \( \omega_{10} \). It serves to find a final estimate of \( \omega_{10} \) as well as \( a_1 \) and \( b_1 \). \( \bar{x} \), the sample mean, will serve as an estimate of \( \omega_{10} \).
Defining $w_1^*, a_1^*$ and $b_0^*$ as final estimates of $w_1$, $a_1$ and $b_1$, and

$\tilde{\mu}_1(=X)$ as an estimate of $\mu_1^*$, we find that

$\hat{\mu}_1 = 5.30486$

$w_1 = 0.2305006$

$a_1 = 0.246352$

$\hat{b}_1 = -0.00147534$

with a residual variance of 0.1025 (a reduction of 22%).

A new time-series is now found by forming the residuals

$e_t = x_t - \tilde{\mu}_1 - a_1 \cos(w_1^* t) - b_0 \sin(w_1^* t)$

The periodogram (tapered 20%) of the new series $\{e_t\}$ is given in figure 9.12. The sample sdf (using a Parzen(b) window with truncation point $M = 60 = 40\%$ of $N$) is given in fig. 9.13.

From both of these plots we now see that the angular frequency corresponding to $w_{10}$ has been 'modelled out' of the data. (Note that $w_{10}$ corresponds approximately to a period of 26).

The 'power' at frequencies $w_9$ and $w_{30}$ now becomes more apparent, thus reinforcing the suspicion of further seasonal components.

(Note that for the sample sdf, the 'numbered' axis represents the frequencies $w_j' = 2^{-j/N}$ (i.e. not $N'$) since $w_{128} = w_1' \rightarrow w_{128}$ corresponds to $-1$ in the periodogram, $w_{128}$ corresponds to $0).$ This power is particularly evident in the sample sdf.

To remove any power at $w_{20}$ in the periodogram (or $w_{11}$ in the sdf) use

$w_{20} = 2^{11} \times 20/256$

$= 0.190473851$ ($w_{20}$ corresponds to a period of 13)

as an initial estimate of $w_{20}$ in the model.

</tbody>
</table>
\[ x_t = \mu_2 + a_2 \cos(w_2 t) + b_2 \sin(w_2 t) + v_t \]

\[ v_t = \text{stochastic process} \]

Use \( w_{20} \) in the program HIDPER in the same manner that \( w_{10} \) was used. Here we find that:

- \( \hat{\mu}_2 = -0.00308542 = 0 \)
- \( \hat{w}_2 = 0.4776025 \)
- \( \hat{a}_2 = 0.169991 \)
- \( \hat{b}_2 = 0.0327472 \)

with a residual variance of 0.0859 (a reduction (overall) of 35%).

Form the (new) time-series:

\[ x_t = \hat{\mu}_2 - \hat{a}_2 \cos(w_2 t) - \hat{b}_2 \sin(w_2 t) \quad t = 0, \ldots, 149 \]

The periodogram (tapered 20\%) of the new series as well as the sample sdf (using the Tukey-Hamming window - see section 4.3.1, equation (4.22) - and truncation point \( M = 75 = 50\% \) of \( N \)) are given in figures 9.14 and 9.15 resp. (The use of different windows is no reflection of inadequacy, but rather just serves as an illustration of the different windows).

Of the three frequencies identified initially as having potential power, two have been removed - namely \( w_{10} \) and \( w_{20} \) (and in the sdf \( w_6 \) and \( w_{11} \)). The final frequency noted in the periodogram given in fig. 9.9 (i.e the periodogram of the transformed data, no components removed) is \( w_3 \) (or \( w_3 \) in the case of the sdf).

It should not be too surprising to see then that the periodogram and sdf in figures 9.14 and 9.15 display power at this frequency. Thus we must remove the component associated with this frequency i.e. model

\[ x_t = \mu_3 + a_3 \cos(w_3 t) + b_3 \sin(w_3 t) + v_t \]

\[ z_t = \text{stochastic process} \]
Fig. 9.14 \( \log_{10} \) of the periodogram of the (twice) de-tined trans-
formed data (201 tapering)
Fig. 9.15. Spectrum estimate of the (twice) de-sined transformed data (Tukey-Hamming window, truncation point 75)
Using \( w_2 = 2^{10} \times 5/256 \)
\[ = 0.122718463 \]
as an initial estimate of \( w_3 \) in HIDPER, we find that
\[ \hat{\omega}_3 = 0.00250543 = 0 \]
\[ \hat{\nu}_3 = 0.1251879 \]
\[ a_3 = 0.0518517 \]
\[ b_3 = -0.143498 \]

[Note that \( w_2 \) and \( w_3 \) correspond approximately to a period of 52]

Create the new time-series \( e_t \) by
\[ e_t = r_t - \hat{\omega}_3 - a_3 \cos(\hat{\omega}_3 t) - b_3 \sin(\hat{\omega}_3 t) \]
\[ t = 0, 1, \ldots, 149. \]

\( e_t \) is a time-series which has three seasonal components removed.

These components correspond to periods of 13, 26 and 52. \( e_t \) has
a sample variance of 0.0741 a reduction of 44\% from the original variance of the log-transformed series of 0.131476.

Instead of performing this third sequential removal, it
is possible, using \( w_{10} \), \( w_{20} \) and \( w_9 \) (as estimates of \( w_1 \), \( w_2 \) and \( w_3 \))
in HIDPER to obtain \( e_t \) in one step
i.e. model
\[
\begin{align*}
\hat{r}_t &= \log_{10} \text{ of original data} \\
\hat{r}_t &= \sum_{j=1}^{3} \left( a_j \cos(w_j t) + b_j \sin(w_j t) \right) + \xi_t \\
\xi_t &= \text{residual error}
\end{align*}
\]
From HIDPER, we find

\[
\begin{align*}
\mu &= 5.30387 \\
\bar{w}_1 &= 0.2331302 \\
\bar{w}_2 &= 0.4777789 \\
\bar{w}_3 &= 0.1239148 \\
\bar{a}_1 &= 0.234516 \\
\bar{b}_1 &= 0.027696 \\
\bar{a}_2 &= 0.166452 \\
\bar{b}_2 &= 0.0320354 \\
\bar{a}_3 &= 0.0417698 \\
\bar{b}_3 &= -0.150152
\end{align*}
\]

and using these values in DETRND we find the sample variance of \( \frac{c_0}{\cdots \hat{c}_{149}} \) is 0.0738. Thus we have a reduction in variance of 44%.

This 'de-sining' procedure could have been stopped after removing the first component (corresponding to a period of approximately 26) which gave a reduction in variance of \( \frac{23}{23} \). When three components are removed (corresponding to approximate periods of 26, 13 and 52) there is a variance reduction of \( \frac{23}{23} \) i.e. the latter two components account for \( \frac{23}{23} \) of the variability in the data. Obviously, this removal of cycles could be continued, however this may lead to the inclusion of an excessive number of model parameters (some possibly redundant). The analyst must decide at this stage how closely he/she wishes to follow the principle of parsimony.

The periodogram (no tapering) of the data (residuals) with 3 seasonal components removed simultaneously is given in figure 9.16. According to the values given in equation (9.1), we have
Fig. 9.16 log$_{10}$ of the periodogram of the (thrice) de-wined transformed data.
\[ w_1 = 0.2331302 \]
\[ w_2 = 0.4777789 \]
\[ w_3 = 0.1239148 \]

(corresponding to periods of 26.95, 13.15 and 50.7\( \pi \) resp.) and these will correspond to abscissae 9.50, 19.47 and 5.05 (resp.) in the periodogram i.e. \( j = 9.50, 19.47 \) and 5.05 in \( w_j = 2\pi j/N \)

(N' = 256) will yield \( w_1, w_2 \) and \( w_3 \) (to 4 decimal places).

From the periodogram in Figure 9.16, we see that there appears to be 'holes' at the abscissae 5.7(\( \pi \)) and 19 thus denoting the removal of \( w_1, w_2 \) and \( w_3 \) (see Bloomfield (1976), p. 80).

The peaks in this periodogram all occur (approximately) at multiples of 9.50, 19.47 and 5.05 thus reinforcing the assumption of additive seasonal components (see note (vii) section 3.4.1 or Bloomfield (1976), pg. 80).

However as a result of leakage and other factors (namely additional seasonal terms) some of these peaks may have magnitudes which are unacceptably large - for example additional seasonal terms may in fact have ordinates which correspond to a multiple of one of the ordinates of the seasonal components removed. Thus to be doubly certain no 'extra' (significant) seasonal terms are influencing the data (residuals), it is advisable to also examine the spectral estimate of the residuals. Spectral estimates (using the Tukey-Hanning window with truncation points \( M = 30, 60 \) and 75 (20%, 40% and 50%, resp.) - any values above or below these truncation points seemed to produce spectra which were either too 'smooth' or too 'rough' - are given in figures 9.17 - 9.19.

As the truncation point increases, peaks become more significant (pronounced). These peaks, although not as pronounced as
Fig. 9.17. Spectrum estimate of the (thrice) de-sined transformed data (Tukey-Hanning window, truncation point 30).
The spectrum estimate of the (thrice) desined transformed data (Tukey-Hanning window, truncation point 60)

those corresponding to the peaks are removed, are also visible in the spectral estimates of the log₁₀ of the data (see figures A19.5 - A19.10) - however they will obviously account for less of the variability in the data (the peaks in figs. 9.17 - 9.19 have such large magnitudes now since they account for a 'large' amount of the variability in the residuals i.e. in the residual variance).

The peaks may be 'removed' from the spectrum of the residuals but as mentioned earlier, since one must decide on whether to adhere to the principle of parsimony, the choice is the analysts. In our case, we shall leave the data (i.e. the residuals) as they stand. The residuals will now be analysed using Box-Jenkins techniques.

9.4 THE BOX-JENKINS ANALYSIS

9.4.1 STATIONARITY

The first stage of the Box-Jenkins analysis consists of determining whether the residuals (referred to from here on as the data) are stationary. To do this, both the procedure of Hill and Woodworth (1980) - see section 7.1, equation (7.6)) - and a visual examination of the acfr of the residuals, will be given.

The first few results of the Hill-Woodworth method are given in table 9.2. (The maximum allowed degree of nonseasonal differencing was 2, of seasonal differencing, 1, and the maximum allowed seasonal base was 52). Recall that the degree of differencing, producing the minimum variance, is defined as 'optimum'.

See 'Comment' at the end of the chapter on page 214.
Table 9.2

DS = degree of seasonal differencing
DNS = degree of nonseasonal differencing
SB = seasonal base

</tbody>
</table>

(the remaining results may be neglected - note how the variance is strictly increasing).

From Table 9.2 it is is clear that no differencing is required to produce minimum variance. Note that the second-best result occurs when seasonal differencing (once) with a seasonal base of 19 is applied. A seasonal base of 19 (or period of 19) should result in a peak in the spectrum of the residuals near 7 and a peak in the periodogram near ordinate 13 - this is exactly what occurs. To obtain these values recall that periods in the spectrum and periodogram are derived from

\[
\text{period} = 2^{\frac{m}{w}}
\]

and

\[
\text{spectrum} = 2^{\frac{j}{N}}
\]

\[
\text{periodogram} = 2^{\frac{j}{N'}}
\]

\(N' = \text{next power of 2 above } N\)
The residual acrf is given in figure 9.20.

The largest ordinate occurs at \( j = 19 \) (reinforcing the suspicion of some seasonality with period 19). Other than this lag, there seems to be no other lag which may hint at some nonstationarity and even so, the acf at lag 19 can just be reflecting the necessity for a seasonal component in the Box-Jenkins model.

Due to the general size of the acf's, one may suspect that in fact the residuals are pure white noise. To check this, note that

\[
V(r'_k) = \frac{1}{\hat{\sigma}^2} \left[ 1 + \sum_{i=1}^{q} \frac{2}{i} \left( \frac{1}{i} \right)^{2} \right] \quad k > q
\]

(9.2)

where \( q \) is some integer (see appendix A3 or Box and Jenkins (1976), pg. 34).

If the whole series is white noise, then \( q = 0 \) in (9.2) and

\[
V(r'_k) = \frac{1}{\hat{\sigma}^2} \quad \text{for all } k > 0
\]

\[ \hat{\sigma}^2 = 0.006 \text{ in our case} \]

The corresponding standard error is 0.08165 (\( = 0.008 \)).

Now if \( N \) is large then \( r'_k \sim \mathcal{N}(0, \frac{1}{N}) \) \( k \) (see appendix A13 or Anderson (1942)) when the data are white noise. Thus 95% confidence bounds for the \( r'_k \) would be \( \pm 2/\sqrt{N} \) (approximately). In our case this results in 0.1633 and -0.163.

Any \( r'_k \) falling outside these limits would seem to indicate a non-white noise process. The only value (lag) at which this occurs is

at \( j = 19 \). Beyond lag 19, the acrf would appear to be negligible (i.e. \( \hat{\phi}_k = 0 \) for \( k > 19 \) (and in fact also for \( k < 19 \))).

In summary then, the data would appear to be stationary since

(a) no differencing (according to the method of Hill and Woodworth (1980)) is required

and

(b) the acrf appears to be damping out to zero, the only problem spot occurring at lag 19 (but this could indicate the necessity for a seasonal component in the model).

### 9.4.2 MODEL IDENTIFICATION AND VERIFICATION

A plot of the partial autocorrelation function is given in figure 9.21, and plots of the inverse acrf and inverse pacrf (i.e. iacrf and ipacrf) - see section 7.2.1 pg. 130 - are given in figures 9.22 and 9.23 resp. In all three plots, the dominant lag would appear to be 19. Besides this lag, there appears to be no power at any of the other lags.

The same technique for testing for whiteness of the acrf can be used in the pacrf - again only lag 19 appears to be significant.

Suppose for the moment, we ignore the dominant lag 19. By using the techniques described in section 7.2 or by using an automatic model selection procedure (on the computer), it may be possible to identify any ARMA \((p,q)\) models \((p,q \leq 5)\). This could be done by generating all possible ARMA \((p,q)\) models \((p,q \leq 5)\) and choosing the model with the minimum residual variance as best-fitting - Akaike's AIC will take the number of parameters in the model into account (see section 7.4.2)).

The 'best' model then turns out to be an AR(3) model, which has

**Fig. 9.23** Inverse partial autocorrelogram of the (thrice) de-sined transformed data

**Fig. 9.22** Inverse autocorrelogram of the (thrice) de-sined transformed data
parameters

\[ \begin{align*}
\phi_1 &= 0.1578 & \text{S.E.} &= 0.0817 \\
\phi_2 &= -0.1046 & &= 0.0824 \\
\phi_3 &= 0.1616 & &= 0.0826 \\
\sigma^2 &= 0.07017 \\
\end{align*} \]

A plot of the residual autocorrelation function is given in figure 9.24 with associated 99\% confidence levels (the first column of data represents the residual acr's and the second column the upper asymptotic confidence levels - the lower levels follow by symmetry [see, for example, Hipel et al (1977)]).

All the acr's except the one at lag 19, fall within these significance levels - thus indicating 'power' at lag 19. This lag could be removed by 'overfitting' (see, for example, Hipel et al (1977)) i.e. instead of fitting an AR(3) model fit an AR model which incorporates \( \phi_1, \phi_2, \phi_3, \text{ and } \phi_{19} \) [this overfitting might be attempted if the partial acr of the 'data' had significant, but decreasing lags at 1, 2, 3 and 19]. However, note that a period of 19, besides being doubtful, makes no intuitive sense (as do 13, 26 and 52) and is difficult to explain. When attempted, this model (i.e. nonzero coefficients at \( \phi_1, \phi_2, \phi_{19} \)) only produced a white noise variance estimate of \( \sigma^2 = 0.066705 \).

Several other over-fitting models were attempted and these (and their white noise variance estimates) are listed in table 9.3.

</table>
Another way of removing the 'power' at lag 19 is to model a seasonal parameter with period 19. It is unlikely that any periodicity or seasonality would entail more than one AR or MA parameter so I limited $P_S$ and $Q_S$ to maximum values of one and tried several models. The 'best' models are listed in Table 9.4.

Table 9.4: ARIMA models

</table>

(above notation represents

\[ (P,D,Q)(P_S,D_S,Q_S)_{SB} \]

$SB$ = seasonal base

$D$ = degree of nonseasonal differencing

$D_S$ = degree of seasonal differencing

AIC = Akaike's Information Criterion

$P,P_S$ = nonseasonal and seasonal AR orders

$Q,Q_S$ = nonseasonal and seasonal MA orders)
Another way of removing the 'power' at lag 19 is to model a seasonal parameter with period 19. It is unlikely that any periodicity or seasonality would entail more than one AR or MA parameter so I limited $P_S$ and $Q_S$ to maximum values of one and tried several models. The 'best' models are listed in table 9.4.

### Table 9.4: SARIMA models

<table>
<thead>

<td>*</td>
<td>0.06402</td>
</tr>
</tbody>
</table>

The above notation represents $(P,D,Q)(P_s,D_s,Q_s)^{SB}$

- SB = seasonal base
- $D$ = degree of nonseasonal differencing
- $D_s$ = degree of seasonal differencing
- AIC = Akaike criterion
- $P,P_s$ = nonseasonal and seasonal AR orders
- $Q,Q_s$ = nonseasonal and seasonal MA orders
The residual autocorrelograms of the four models marked * are shown in figures 9.13 - 9.28 resp. Since for all 4 models, all the residual acr's fall inside the 1% significance limits, all the models are 'acceptable'.

The best model, i.e. the model with minimum AIC, would appear to be $(3,0,0)(1,0,1)$. The one-step-ahead forecasts of the desined data, based on this model, are given in table 9.5. As a result of the large amount of unexplained variability in the data, (the desining procedure accounts for about 44% and the B-J node an additional 11% i.e., only about 55% of the variability in the data can be modelled - the rest is due to white noise) the forecasts are not very accurate.

An estimate of the spectrum (using the Parzen (l) window - see section 4.3.1, equation (4.25) - and truncation point $M = 60 = 0.4 \times N$) of the final residuals (i.e. log of data minus sinusoids minus Box-Jenkins model) is given in figure 9.29. This plot seems to be dominated by several peaks and troughs, with the major peak occurring at lag 31 (which corresponds, assuming seasonality, to a period of 4 or 5 i.e. monthly periodicity). However even this peak does not seem to have any overall dominance in the spectrum. It does not seem worthwhile trying to model the data any further.

Thus it would appear that the best model is

$$Z_t = \log_{10} X_t$$

with

$$Z_t = \text{constant} + 3 \text{ sinusoids} +$$

Fig. 9.29  Spectrum estimate of the residuals (Parzen (b) window, truncation point 60)
(see equations (9.1) for \( \mu, a, b_i, a_j \)) where \( \varepsilon_t \) is such that

\[
(1 - \phi_1 B)(1 - \phi_2 B - \phi_3 B^2)\varepsilon_t = (1 - \phi_1 B) \eta_t
\]

and \( \eta_t \) are white noise variables with \( V(\eta_t) = 0.05988 \) and

\[
\begin{align*}
\phi_1 &= -0.71 \\
\phi_2 &= -0.0553 \\
\phi_3 &= 0.1144 \\
\phi_4 &= -0.102 \\
\phi_5 &= 0.1609
\end{align*}
\]

(with associated standard errors

0.1253

0.0786

0.0452

0.0440

0.0840)

All these numerical values were obtained from the program BJES described in appendix A18, which is a program for obtaining parameter estimates in Box-Jenkins models.

9.4.3 SIMULATION

In figures 9.30 - 9.33 are the spectral estimates (using the Parzen (b) window and truncation point \( M = 67 \)) for the stretch of data \( x_{31}, \ldots, x_{104} \) in the four cases

(i) original data

(ii) sinusoid simulation

</table>
Case (ii) above, is just a simulated data set involving $u$ and the three sinusoidal components modelled in the data. Cases (iii) and (iv) take this simulated sinusoid and add the stochastic element, modelled by the Box-Jenkins process $(3,0,0)(1,0,1)^{19}$, obtained from either the 1-step-ahead forecasts or just a simulation of the process.

Except for the sinusoid by itself (i.e. (ii)) the remaining spectra have a relatively strong resemblance to one another. However due to the large amount of unexplained variability in the data, this resemblance cannot be strengthened. It is interesting to note that the simulated stochastic element has the closest resemblance to the spectrum of the original data, (more so than the forecasted element) and it may be wiser to use a simulated stochastic process (with $N(0,\sigma^2_a)$ random errors) as a forecasting model.

9.4.4 AR MODELLING AND AR SUBSET MODELS

Due to the low degree of variability explained by the model fitted up to this point, I have tried using McClave's chi-squared technique (see appendix A15) for fitting AR models to the $\log_{10}$ of the data. The results, for a maximum model size of AR(30), are given in table 9.6 (by using the programs AUTO and AUTOAR described in appendix A18). For each AR(k) model, $k = 1, \ldots, 30$, the values of the CAT and AIC statistics are given (see section 7.4.2 pg 144) (RV = residual variance, and is obtained using backforecasting).
Table 9.6 AR modelling (using backforecasting)

</tbody>
</table>
From these results we obtain the following

CAT best model : AR(4)
AIC best model : AR(3)

(using the CAT criterion, one may choose a 'best' model, or 'better' model, as occurring at any relative minimum - the above model, i.e. AR(3), is for the overall minimum CAT value).

Thus it would seem that an AR(3) process is the best AR model to fit to the $\log_{10}$ of the data. However this doesn't explain very much of the variability in the data. (It is also pointless trying to fit subset AR models since p is so small).

Similar results are obtained by applying this procedure to the $\log_{10}$ data minus sinusoid (1) (corresponding to a period of 26) - i.e. an AR(3) is the best fitting AR model (based on Akaike's criteria). In this case, the residual variance (of the AR(3) model) is 0.0363.

9.5 COMMENT

9.5.1 MIXED SPECTRA

Suppose we have a process $x_t$, which we intend modelling as $x_t = \text{deterministic cycles} \times \text{stochastic process}$

$= \text{harmonic component} \times \text{general linear process}$

$= \sum_{i=1}^{m} A_i \cos(w_i t + \phi_i) + e_{t-u}$

i.e. the best model when harmonic analysis is not used
where \( E(t^0) = 0 \) (independent \( \forall t \))
\[ E(t^2_0) = 1 \]
\[ E(t^2_0) < \infty \]
and
\[ E(x^2_0) < \infty \]

Suppose \( \{y_t\} \) has sdf \( h_y(w) \) and \( \{z_t\} \), \( h_z(w) \). If \( \{y_t\} \) and \( \{z_t\} \) are uncorrelated processes, then
\[ h_X(w) = h_y(w) + h_z(w) \]
and \( \{x_t\} \) is said to have a \underline{mixed spectrum} if \( h_X(w) \) is not a constant.

All the sampling properties of the sdf and periodogram were derived for the special case where \( \nu_z(r) = 0 \ \forall r \neq 0 \). For instance, in chapter three, when searching for harmonic components, \( z_t \) was assumed to be white noise (and hence has a constant spectrum).

The null hypothesis of no harmonic components present was put forward and then \( m \) in
\[ y_t = \sum_{i=1}^{m} \cos(wt + \beta_i) \]
was determined by testing the periodogram ordinates (in order of magnitude) until we failed to get a significant result.

Now it may happen that \( \{z_t\} \) does not have a constant spectrum and might only have power at one frequency, \( w_0 \) say. If \( \{y_t\} \), or more correctly, \( h_y(w) \), does not have power at \( w_0 \), a periodogram test (or spectrum test) may incorrectly indicate a harmonic component at \( w_0 \). So if \( \{z_t\} \) is not a white noise process, then any test for periodogram ordinates (see appendix A5 for example) is not strictly applicable - thus the procedure, and conclusions, of the analysis of the data used in this chapter, may be incorrect.
What is needed is a test (under the assumption that we have a mixed spectrum) which will separate, or determine the existence of, the discrete spectrum.

If a discrete spectral component is detected, its parameters must be estimated (i.e., the amplitude and frequency). The contribution of this harmonic term must then be removed from the data and a test applied for another harmonic component in the residuals. This must be continued until no further harmonic components are indicated.

Several tests for the existence of the discrete spectrum are given in Priestley, 1981, pg. 617*. The one I have used is termed the \( P(\cdot) \) test and is described fully in Bhansali (1979) and Priestley (1982a,b). It is summarized here without proof.

The \( P(\cdot) \) test

Suppose we model

\[
x_t = \sum_{i=1}^{m} y_t = A_i \cos(\omega_i t + \eta_i)
\]

\( \eta_i \sim U(-\pi, \pi) \) (i.e., uniform distribution on \((-\pi, \pi))\)

a general linear process

\( H_0 \): all the \( A_i \) are zero.

If \( H_0 \) is true, the acrf of \( x_t \) should eventually damp out to zero. However, if one (or more) of the \( A_i \) are nonzero, then the acrf will not damp out and in fact its tail will behave like a linear combination of cosine terms of the same (or similar) frequency as those of the harmonic components.
Let $h_i(w)$ and $h_j(w)$ be two spectral estimates of $h_m(t)$ where $i$ and $j$ denote the truncation points of the spectral windows and $j > 2i$. The point $i$ is such that $y^i_t$ has acvf with

$$y^i(t) = 0 \quad |t| > i$$

If we are searching for harmonic components, we may do this by performing an harmonic analysis of the tail of the acvf so examine

$$P(\lambda) = h_j(\lambda) - h_i(\lambda)$$

$$\lambda = \frac{2\pi p}{N}$$

$$p = 0, 1, 2, \ldots, \left[\frac{N}{2}\right]$$

$$N > j > 2i$$

If some of the $A_s$ are nonzero then a plot of $P(\lambda)$ will exhibit several well defined peaks. Testing each peak in order of frequency, and supposing the first peak is at $\lambda_0$, form

$$J_q = \left[ \frac{N}{\lambda(1,j)} \right] \frac{1}{2} \sum_{s=0}^{N/2} \left( \frac{2\pi s}{N} + \delta \right) \hat{c}_q \quad q = 0, \ldots, \frac{N}{2}$$

where $P(\cdot) = P(\cdot)/c_0$

$c_0$ = sample variance

$$\hat{c}_q = \left[ \frac{1}{8\pi} \sum_{u=1}^{2i} r_u - \sum_{u=21}^{2i} r_u \right]$$

$r_u$ = acvf at lag $u$

$s$ is such that $0 < s$ and $\frac{2\pi s}{N} + \delta = \lambda_0$ some integer $s$

$(i,j)$ depends on the form of the spectral windows $h_i(w)$ and $h_j(w)$.
For the special case where $h_1$ and $h_j$ are both Bartlett spectrum estimates given by equation (4.18)

$$\Lambda(i,j) = \frac{2}{3} j - \frac{4}{3} i + \frac{2i^2}{3j}$$

(Priestley, 1962a)

If $\max \left( \frac{\Lambda(i,j)}{\Lambda(i,j)} \right) > \alpha_0$ where $\alpha_0$ is the upper 100% point of a $N(0,1)$ distribution, then the peak at $h_1$ is significant at the $\alpha$ level of significance.

For more details on the theory behind the test, see Priestley (1962a,b).

**Application of the P(*) test**

Priestley's P(*) test was applied to the logarithms of the data over the section of interest (i.e. $x_1, x_2, \ldots, x_{150}$).

Several truncation points were used, namely $i = 7, 17, 22$ and $58$ and these represented the lags at which I felt the acrs were $0$.

For each $i$ (the lower truncation point), several $j$'s (the upper truncation points) were used and these were such that $j > 2i$ and represented the end of a 'cycle' in the acrf.

* e.g., $i = 22$, $j = 48, 53, 59$

* $i = 58$, $j = 120$

The plots of $P(*)$ for $i = 22$ and $j = 53, 59$ are given in figures 9.34 and 9.35 resp. In both cases, the peak at $k = 6$ was tested and I obtained

$$J_q(22, 53) = 2.94$$

$$J_q(22, 59) = 3.01$$

i.e. significant at the 1% level. Similarly, with $i = 58$ and $j = 120$, a value of

$$J_q(58, 120) = 2.09$$

was obtained for the peak at $k = 6$ - i.e. significant at the 5% level. (In this case, a peak at $k = 3$ was the first major peak

Fig. 9.35 $P(\lambda)$ with lower truncation point 22 and upper truncation point 59
and this had a $Q_0$ value of 2.16 - however if we ignore this temporarily and test $k = 8$ we obtain the above $Q_0$ values.

A peak there, i.e., at $k = 8$, seems coherent in the data, and such a peak corresponds to a seasonal component of frequency,

$$Q_0 = 0.20 (100 - 0.80)$$

(corresponds to a period of 28 or 24 - exactly the same result as obtained using periodogram analysis).

Removing this harmonic component from the data, it was now necessary to perform the whole test over again.

Consider a (lower) transition point of 55 (-1) and upper value of 110 (1) (the choice of 55 seems reasonable from the appearance of the data, of this new data set, given in Figure 2.39).

In this case, the first dominant peak appears at lag $k = 3$.

Testing for this, I obtained

$$Q : (55,110) = 2.73$$

- again highly significant.

Similarly, using $Q = 70$ and $Q = 135$, I obtained

$$Q : (70,135) = 2.00$$

(still significant at the 2% level)

Thus it would seem that an harmonic component corresponding to a frequency of $Q_0 = 2.16 (100 - 0.80)$ (and corresponding to a period of approximately 31) is evident in the data; this is also supported by the failure of the test to damp out - it seems to be oscillating fairly regularly.

Removing this component and performing the P(1) test again, a peak at lag $k = 11$ is dominant and when tested, is also significant.
Autocorrelogram (up to lag 148)
of the transformed data minus the harmonic component detected by the P(k) test.
The peak at \( k = 11 \) corresponds to an harmonic component with frequency \( 11 \cdot 2\pi 150 = 0.461 \) and approximate period of 13. No more peaks were found to be significant.

Thus the \( P(\cdot) \) test seems to support the conclusions (and strictly speaking, the incorrect procedure) of the harmonic analysis.

However, I still view these conclusions with suspicion since

(a) Priestley's \( P(\cdot) \) test was designed so that peaks are tested in order of frequency and this should prevent one obtaining spurious significant results (cf Priestley (1962 a,b)) - however Bhansali (1979) has shown that it is possible to get spurious results.

and

(b) due to the large variability in the data, it is not really possible to assess whether the rises and falls in the data are equal - Galbraith (1977) notes that if the data are asymmetrical as far as the rises and falls go (for example the data may always require about 10 values to reach a peak from a trough, but may only have about 5 values from a peak to a trough and if this asymmetry is not incorporated into the model, then this asymmetry will show up as minor peaks (in the sdf) at frequencies which are multiples of the fundamental frequency.

I am fairly confident that an harmonic term corresponding to a period of 26 is evident in the data - but if the data are 'asymmetrical' as described above, then peaks in the sdf will occur at multiples of approximately \( \omega = 0.25 \) - this may account for peaks at \( \omega = 0.46 \) and \( \omega = 0.13 \).
9.5.2 LOGARITHMIC TRANSFORMATIONS

It is unreasonable to assume that our process \( \{x_t\} \) can always be
modelled by an additive form
\[ i.e. \quad x_t = y_t + z_t. \]
Another obvious possibility is a multiplicative model
\[ i.e. \quad x_t = y_t^* z_t. \]
By taking logarithms, any multiplicative model is converted into
an additive form. However we may incorrectly assume the data have
a multiplicative form, when they really have an additive form, and
then a logarithmic transformation is not really applicable. However
the logarithmic data should still have a form which is approximately
additive.

Parzen (1978) states that if the data do not appear to be
normally distributed, one may perform a log transformation (or any
other memoryless transformation) since such transformations often do
not change the overall shape of the data. When this is true, it
then seems reasonable to assume that if the data originally had an
additive form, by taking logarithms this should not change things
dramatically (obviously one of the exceptions being data which are
\( = 0 \), negative or in the interval \((0,1)\)).

Thus I am tempted to suggest that generally the form of the
model will not change if logarithms of the original data are taken.
9.6 CONCLUSION

The model I finally decided upon was the following:

\[ z_t = v + \sum_{j=1}^{3} \left( a_j \cos(t w_j) - b_j \sin(t w_j) \right) + e_t \]

(see equation (9.1) for \( a_j, b_j, w_j \))

\[((1 - \beta^{10})(1 - \beta^{10})^{1/2} - \beta^{10})x_t \approx (1 - \beta^{10})a_t \]

(see pg.207 for these parameter values)

and \( Z_t = \log_{10} x_t \)

\( x_t \) is the original data set

\( a_t \) is a white noise series with \( V(a_t) = 0.0598 \)

\( \text{Cov}(a_t, a_s) = 0 \quad \forall t \neq s \)

\( \text{E}(a_t) = 0 \quad \forall t \)

The model turned out to be very disappointing in terms of variance reduction. This does not detract from the power of the techniques presented - it may be that the data used consisted mainly of white noise (this will account for the small reduction in variance i.e. only 55%).

It is probable that the residuals may be modelled further, however this will only lead to an increase in the number of parameters in a model already containing a large number. By including more parameters, the variance will not be reduced substantially (see, for example, section 9.4.4) and we may also have the problem of overfitting (if this had not already been done in the final model given).
A more successful application of this de-sining/BJ modelling procedure has been performed on the Canadian lynx data, i.e., the annual trapping of lynx - this data is given in Campbell and Walker (1977) and the application may be found in Bhansali (1979). For an application of subset autoregression models to the same data see Gabr and Subba Rao (1981). This data set shows how successful this modelling procedure can be and atones for the data analysed in this chapter.

If this airline data consists mainly of white noise, as I believe it does, then it is unlikely that any model, of the types described, will achieve a variance reduction (i.e., fit) of over 70%.
APPENDIX A1: STOCHASTIC LIMITING OPERATIONS

1. Let $X_1, X_2, \ldots$ be a sequence of r.v. The sequence $X_i$ converges in mean square iff there exists a random variable $X$ such that

$$\lim_{i \to \infty} E[(X_i - X)^2] = 0$$

This is written as

$$\lim_{i \to \infty} X_i = X.$$  

2. $X(t)$ is stochastically continuous at $t = t_0$ if

$$\lim_{t \to t_0} X(t) = X(t_0)$$

i.e. iff

$$\lim_{t \to t_0} E[(X(t) - X(t_0))^2] = 0$$

3. If $X(t)$ is stationary with variance $\sigma^2$ and acrf $C(\tau)$, then

$$E[(X(t) - X(t_0))^2] = \sigma^2 + \sigma^2 C(t)$$

so $X(t)$ is stochastically continuous at $t = t_0$ iff

$$\lim_{t \to t_0} (t - t_0) = 1$$

i.e. iff $\lim_{t \to t_0} C(t) = 0$

i.e. iff $C(t)$ is continuous at $t = 0$.

4. If $C(t)$ is continuous at $t = 0$, it is continuous everywhere (consider $E X(t - t_0)X(t - h) - X(t)$ and use the Cauchy-Schwarz inequality; then assume $C(t)$ is continuous at $t = 0$).
5. $X(t)$ is stochastically differentiable at $t = t_o$ with derivative $X'(t_o)$ iff

$$\lim_{h \to 0} \frac{X(t_o + h) - X(t_o)}{h}$$

exists (and equals $X'(t_o)$)

i.e. iff

$$\lim_{h \to 0} \mathbb{E} \left( \frac{X(t_o + h) - X(t_o)}{h} \right)^2$$

exists

But

$$\mathbb{E} \left( \frac{X(t_o + h) - X(t_o)}{h} \right)^2 = \frac{2}{h^2} (1 - o(h))$$

for $X(t)$ to be stochastically differentiable, we require

$$\lim_{h \to 0} \frac{1 - o(h)}{h^2}$$

i.e. that $o'(0)$ exists and is zero.

6. Consider $\int g(t)X(t)dt$ where $g(t)$ is a deterministic function.

Now consider an arbitrary (finite) set of points $(t_0, \ldots, t_n)$ in $(a,b)$ and define the Riemann integral as

$$\lim_{\max (t_i - t_{i-1}) \to 0} \sum_{i=1}^{n} g(t_i)X(t_i)(t_i - t_{i-1})$$

Now this limit exists in mean square iff

$$\int_a^b \int_a^b g(t)g(s)(t-s)dsdt$$

exists as a double Riemann integral.

In a similar manner Riemann-Stieltjes integrals involving stochastic processes may be defined.

For two deterministic functions $g(t)$ and $F(t)$, the Riemann-Stieltjes integral

$$\mathbb{I} = \int_a^b g(t)dF(t)$$

is defined as the limiting value of
\[ \sum_{i=1}^{n} g(t_i) \left( \tilde{F}(t_i) - \tilde{F}(t_{i-1}) \right) \]

as \( \max (t_i - t_{i-1}) \to 0 \)

So a Riemann-Stieltjes integral of the form

\[ \int_{a}^{b} g(t) dX(t) \]

may now be defined as the mean square limit of

\[ \sum_{i=1}^{n} g(t_i) \left| X(t_i) - X(t_{i-1}) \right| \]
APPENDIX A2: THE VARIANCE AND COVARIANCE OF VCVF ESTIMATES

Suppose we have a (second-order) stationary process \( X_t \) and w.l.o.g., assume \( \mu \), the mean of \( X_t \), is 0 i.e. \( E(X_t) = 0 \) \( \forall t \)

So \( r \) as defined by (2.28), reduces to

\[
\hat{c}_r = \frac{1}{N} \sum_{t=1}^{N} X_t X_{t+r}
\]

and \( E(\hat{c}_r) = (1 - \frac{1}{N}) \gamma(r) \forall r \) (by (2.29))

If \( r > 0 \) and \( r + k > 0 \), (and both are \( \leq N-1) \)

\[
\text{Cov} \left( \hat{c}_r, \hat{c}_{r+k} \right) = E(c_r c_{r+k}) - E(c_r)E(c_{r+k})
\]

\[
= \frac{1}{N^2} \sum_{t=1}^{N-r} \sum_{s=1}^{N-r-k} X_t X_{t+r} X_s X_{s+r+k} \gamma(r) \gamma(r+k)
\]

Now a standard result for quartic forms states that if \( E(X_t) = 0 \) \( \forall t \), then (by Isserlis (1918))

\[
E(x_t x_{t+r} x_s x_{s+r+k}) = E(x_t x_{t+r})E(x_s x_{s+r+k}) - E(x_t x_s)E(x_{t+r} x_{s+r+k}) - E(x_t x_s)E(x_{t+r} x_{s+r+k}) - K_q(s-t,r,k)
\]

(\( K_q(s-t,r,k) \) is the coefficient of \( \frac{(it_1)(it_2)}{t!(r+t)!} \frac{(it_3)(it_4)}{s!(s+r+k)!} \) in \( E(x_1 x_{1+t_1} x_{1+t_2} x_{1+t_3} x_{1+t_4}) \), the multivariate characteristic function, if an expansion in power series exists)

Using this result, (a2.1) reduces to

\[
\text{Cov}(\hat{c}_r, \hat{c}_{r+k}) = \frac{1}{N^2} \sum_{t=1}^{N-r} \sum_{s=1}^{N-r-k} (s-t) \gamma(s+k-t) + \gamma(s+r+k-t) \gamma(s+r-t) - K_q(s-t,r,k)
\]

(a2.2)
Suppose we have a (second-order) stationary process \( X_t \) and w.l.o.g. assume, the mean of \( X_t \), is 0 i.e. \( E(X_t) = 0 \) \( \forall t \)

So \( c_r \) as defined by (2.28), reduces to

\[
v_r = \frac{1}{N-r} \sum_{t=1}^{N-r} X_t X_{t+r}
\]

and \( E(c'_r) = (1 - \frac{(r+1)}{N}) (r) V_r \) (by (2.29))

If \( r > 0 \) and \( r + k > 0 \), (and both are \( \leq N-1 \))

\[
\text{Cov} \left( c'_r, c'_{r+k} \right) = E(c'_r c'_{r+k}) - E(c'_r)E(c'_{r+k})
\]

\[
= \frac{1}{N^2} \sum_{t=1}^{N-r} \sum_{s=1}^{N-r-k} X_t X_{t+r} X_s X_{s+r+k} - (1 - \frac{r}{N})(1 - \frac{r+k}{N}) \gamma(r) \gamma(r+k)
\]

(a2.1)

Now a standard result for quartic forms states that if \( E(X_t^4) = 0 \) \( \forall t \), then (by Isserlis (1918))

\[
\gamma(t, t+r, s, s+r+k) = \gamma(t, t+r) \gamma(s, s+r+k)
\]

\[
= \gamma(t, t+r) \gamma(s, s+r+k)
\]

\[
\gamma(t, t+r, s, s+r+k) = K_4(s-t, r, k)
\]

(where \( K_4(s-t, r, k) \) is the coefficient of

\[
\frac{(it_1)(it_2)(it_3)(it_4)^{r+s+k}}{t:(r+t):s:(s+r+k):}
\]

in \( \ln \Phi(t_1, t_2, t_3, t_4) \), the multivariate characteristic function, if an expansion in power series exists)

Using this result, (a2.1) reduces to

\[
\text{Cov} \left( c'_r, c'_{r+k} \right) = \frac{1}{N^2} \sum_{t=1}^{N-r} \sum_{s=1}^{N-r-k} \gamma(t, t+r) \gamma(s, s+r+k) + K_4(s-t, r, k)
\]

(a2.2)
\[
\begin{align*}
V(c_r') &= \frac{1}{N} \sum_{m=-a}^{b} \left[ \gamma(m) \gamma(m+r+k) \gamma(m-r) - \frac{1}{N} \sum_{m=-a}^{b} \gamma(m) \right] \\
\text{where} \quad a &= -(N-r) + 1 \quad b = N - r - k - 1 \\
\text{and} \quad m > 0 \\
V(m) &= 0 \\
-k < m < 0 \\
-(m+k) < m < -k
\end{align*}
\]

Now if \( \{X_t\} \) is Gaussian, then \( K_q(m,r,k) \) is zero. Letting \( n = 0 \),

\[
V(c_r') = \frac{1}{N} \sum_{m=-a}^{b} \left[ 1 - \frac{m-r}{N} \right] \gamma(m) \gamma(m+r) \gamma(m-r)
\]

For large \( N \),

\[
\begin{align*}
\text{Cov}(c_r', c_r'+k) &= \frac{1}{N} \sum_{m=-a}^{b} \left[ \gamma(m) \gamma(m+k) + \gamma(m+r+k) \gamma(m-r) - \frac{1}{N} \sum_{m=-a}^{b} \gamma(m) \right] \\
\text{if} \quad \gamma(m) = 0 \quad \forall m < 0 \quad \text{(a2.3)}
\end{align*}
\]

\[
\begin{align*}
\text{and} \quad V(c_r') &= \frac{1}{N} \sum_{m=-a}^{b} \gamma(m) \gamma(m+r) \gamma(m-r) \\
\text{if} \quad \gamma(m) = 0 \quad \forall m < 0 \quad \text{(a2.4)}
\end{align*}
\]

i.e. \( V(c_r') \) is of order \( \frac{1}{N} \) for large \( N \).

\textbf{Note}

If \( \{X_t\} \) has a continuous spectrum then we may express (a2.3) and (a2.4) i.t.o. this continuous sdf, \( h(w) \) say.

\[
\begin{align*}
\text{Cov}(c_r', c_{r+k}') &= \frac{2}{N} \int_0^\infty \left( 1 + e^{-2iw} \right) h(w) dw \\
\text{and} \quad V(c_r') &= \frac{2}{N} \int_0^\infty \left( 1 + e^{-2iw} \right) h(w) dw
\end{align*}
\]
So for $r = 0$,

$$V(\hat{\sigma}_0^2) = \frac{2}{N} \sum_{m=-\infty}^{\infty} \gamma^2(m)$$

and so

$$V(\hat{\sigma}_r^2) = \frac{2}{N} \sum_{m=-\infty}^{\infty} \gamma^2(m)$$

$$= \frac{2}{N} \sum_{m=-\infty}^{\infty} c^2(m)$$

Since $c_r' = \frac{N-r}{N} c_r$, the variance and covariance terms for $c_r$ can be found in a similar fashion.

In particular, for $r > 0$

$$V(c_r') = \frac{1}{N-r} \sum_{m=-\infty}^{\infty} \gamma^2(m) + (m-r)\gamma(m-r)$$

(proof not shown)

thus $V(c_r')$ is of order $\frac{1}{N-r}$.
Suppose we have a realization $x_1, \ldots, x_n$ from a second-order zero-mean stationary process $\{X_t\}$. Define $\hat{r}_k$ as in (2.33) and define a function $\delta(x)$ as

$$
\delta(x) = x - E(x)
$$

and

$$
\delta(r_k') = \hat{r}_k \text{ say}
$$

$$
= r_k' - E(r_k')
$$

If we assume $\hat{r}_k$ and $\hat{r}_{k+v}$ are small compared to $E(r_k')$ and $E(r_{k+v}')$, then

$$
E(r_k') = \frac{E(c_k')}{E(\hat{r}_k')}
$$

and

$$
\delta(r_k') = \frac{\delta(c_k')}{c_k'}
$$

$$
= \frac{\delta(c_k')}{c_k'} = \frac{\partial}{\partial x} \left( \frac{c_k'}{x} \right)
$$

$$
= \frac{\delta(c_k')}{c_k'} = \frac{\partial}{\partial x} \left( \frac{c_k'}{x} \right)
$$

$$
= \frac{\delta(c_k')}{c_k'} = \frac{\partial}{\partial x} \left( \frac{c_k'}{x} \right)
$$

so a first-order approximation.

Hence

$$
k \hat{r}_{k+v} \\delta(c_k') \delta(c_{k+v}') = \frac{\gamma^2(0)}{\gamma^2(0)} \delta(c_k') \delta(c_{k+v}')
$$

$$
= \frac{\gamma(0) \delta(c_k') \delta(c_{k+v}')}{\gamma^3(0)} \frac{\gamma(k+v) \delta(c_k') \delta(c_{k+v}')}{\gamma^3(0)}
$$

$$
= \frac{\gamma(k) \delta(c_k') \delta(c_{k+v}')}{\gamma^3(0)} \frac{\gamma(k+v) \delta(c_k') \delta(c_{k+v}')}{\gamma^3(0)}
$$
Taking expectations gives

\[ \text{Cov}(r'_k, r'_{k+v}) = \frac{1}{4} \left[ \text{Cov}(c'_k, c'_{k+v}) - \sigma(k+v)\text{Cov}(c'_k, c'_k) - \sigma(k)\text{Cov}(c'_k, c'_{k+v}) + \sigma(k)\sigma(k+v)\text{V}(c'_k) \right] \]  

(a3.1)

Assuming \( \{X_i\} \) is Gaussian and using (a2.3), then if \( k > 0 \) and \( k = v > 0 \),

\[ \text{Cov}(r'_k, r'_{k+v}) = \frac{1}{N} \sum_{m} \sigma(m)\sigma(m+v) + \sigma(m+k+v)\sigma(m-k) \]

\[ + 2\sigma(k)\sigma(k+v)\sigma^2(m) - 2\sigma(k)\sigma(m)\sigma(m-k-v) - 2\sigma(k+v)\sigma(m)\sigma(m-k) \]  

(a3.2)

If \( \sigma(m) = 0 \) then \( \forall m \neq 0 \)

\[ V(r'_k) = \frac{1}{N} \sum_{m} (m) - \frac{1}{N} \sum_{m} 2(m) - \frac{1}{N} \sum_{m} (m+k)\sigma(m-k) \]  

(a3.3)

If \( \sigma(m) = 0 \) then \( \forall m \neq 0 \)

\[ V(r'_k) = \frac{1}{N} \]

For further details see Bartlett (1946)
APPENDIX A4: THE VARIANCE AND COVARIANCE OF THE PERIODOGRAM

The periodogram, \( I(w) \), can be defined by

\[
I(w) = \frac{N-1}{N} \sum_{h=-(N-1)}^{N-1} c_h^* \cos(hw)
\]

where \( c_h^* \) = sample acvf

(see (3.51) and section 2.4)

For any \( w_j \), \( w_i \) (where \( w = 2\pi l/N \)),

\[
\mathrm{Cov}(I(w_j), I(w_i)) = 4 \sum_{s=0}^{N-1} \sum_{r=0}^{N-1} a(s)a(r) \cos(sw_j) \cos(rw_i) \mathrm{Cov}(c_s^*, c_r^*)
\]

where \( a(0) = 1 \)

and \( a(s) = 2 \quad s \neq 1 \)

If we assume the \( x_t \)'s are independent,

then

\[
K_4(s-t, k, v) = \begin{cases} 
E(X_t^4) & s-t = k = v = 0 \\
0 & \text{otherwise}
\end{cases}
\]

and

\[
\gamma(s) = \begin{cases} 
\frac{2}{X} & s = 0 \\
0 & \text{otherwise}
\end{cases}
\]

(i.e. \( x_t = \sqrt{\frac{2}{X}} \) \( W_t \) where \( W_t \) is a purely random process).

Then \( \mathrm{Cov}(c_s^*, c_r^*) = 0 \quad r = s \)

(see appendix A2)

and

\[
\nu(c_s^* \mid k) = \frac{N-s}{N^2} c_s^4(1 + \frac{K_4}{N}) - 1 - \frac{K_4}{N} \quad (s \neq 0)
\]

where \( K_4 = E(X_t^4) \)

and

\[
\begin{align*}
\gamma(s) &= \begin{cases} 
\frac{2}{X} & s = 0 \\
0 & s \neq 0
\end{cases} \\
\nu(s) &= \begin{cases} 
1 & s = 0 \\
0 & s \neq 0
\end{cases}
\end{align*}
\]
Hence

\[ \text{Cov}(I(w_j), I(w_{\bar{j}})) \]

\[ = \frac{4K}{N} \left( \frac{4C}{N} \left( \frac{2 + 4}{N} \left( 1 - \frac{g}{N} \right) \times \cos(sw_j)\cos(sw_{\bar{j}}) \right) \right) \]

\[ = \frac{4K}{N} \left( \frac{4C}{N} \left( \frac{N-1}{h} \times \frac{h}{(N-1)} \left( 1 - \frac{b}{h} \right) \left( a+b \right) \right) \right) \]

(\text{where } a = \cos(h(w_j-w_{\bar{j}})) \text{ and } b = \cos(h(w_j-w_{\bar{j}})))

- proof not shown, but is similar to that used to find the \( E(I(w)) \)

\[ \text{i.e. (3.53))} \]

\[ = \frac{4K}{N} \left( \frac{4C}{N} \right) \left( \frac{c+d}{c+d} \right) \]

where

\[ c = \frac{\sin^3 \left( \frac{N(w, w_{\bar{j}})}{2} \right)}{\sin \left( \frac{w, w_{\bar{j}}}{2} \right)} \]

and

\[ d = \frac{\sin^3 \left( \frac{N(w, w_{\bar{j}})}{2} \right)}{\sin \left( \frac{w, w_{\bar{j}}}{2} \right)} \]

Hence

\[ \nu(I(w)) = \frac{4K}{N} \times \frac{4C}{N} \times \bar{w} = 1 \]
APPENDIX A5: TESTING THE SIGNIFICANCE OF PERIODOGRAM ORDINATES

A plot of $I(w_j)$, the sample periodogram, against $j$ (or $w_j$), will yield a series of ordinates some of which may be approximately zero. Those which are (nearly) zero will indicate that our model

$$x_t = \frac{1}{N} \sum_{j=0}^{N-1} (a_j \cos(w_j t) + b_j \sin(w_j t)) + c_t$$

$$t = 0, \ldots, N-1$$

$$w_j = 2^{-j}/N$$

does not contain either cosine or sine components at these particular frequencies. However we need an objective test to decide which of the ordinates are not significantly different from zero.

If the $X_t$ are Gaussian, then by the theory of sections 3.5, 3.6, and 3.7.

$$I(w_j) \sim \chi^2_2$$

$j = 0$ and $N$ odd

So $I(w_j)$ has pdf

$$f(x) = \frac{1}{2} e^{-x/2} 0 < x < \infty$$

(i.e. exponential with parameter $\lambda = \frac{1}{2}$)

$$P(I(w_j) < k) = 1 - e^{-k/2} \quad (\text{a5.1})$$

Let

$$\beta = \max \left\{ \frac{I(w_j)}{\chi^2_2} \right\} \quad (N \text{ odd}) \quad (\text{a5.2})$$

then $P(\beta > k) = 1 - (1 - e^{-k/2})^{\frac{N}{2}}$ (since the $I(w_j)$ are independent).

Usually $\frac{1}{\lambda}$ is unknown and we have to estimate it from the data.

From (3.49),

$$E(I(w_j)) = 2 \frac{1}{\lambda} 0 < j = \left(\frac{N}{2}\right) \quad (N \text{ odd})$$
Replacing $\sigma_k^2$ by $s_k^2$ in (a5.2), we obtain the test statistic

$$\max_j I(w_j) = \frac{1}{2[N/2]} I(w_j)$$

(Note that $I(w_j)$ need not be considered since $E(x_j) = 0 \, \forall t$, and $I(w_0) = \sigma_0^2 = (\nu)^2 = 0$)

Ignoring sampling fluctuations in the denominator of $\sigma_k^2$ given in (a5.3), then, asymptotically,

$$P(\delta > k) = 1 - (1 - \frac{k}{N})^{N/2} = \frac{N/2}{e^{k/2}}$$

(for small $e^{-k/2}$ i.e. large $k$ and $N$ not too large)

So our test procedure for the maximum ordinate in the periodogram, consists simply of choosing our significance level $\alpha$ and hence finding $k$ such that

$$P(\delta > k) = \alpha$$

If $\delta > k$ we conclude that

$$\max_j I(w_j) \neq 0$$
Suppose we conclude \( \max \{ I(w_j) \} < 0 \).

What about \( \max \{ I(w_j) \} \) where \( I(w_j) = \max \{ I(w) \} \)?

Omit \( I(w_j) \) from \( \frac{1}{I(w_j)} \) in the denominator of \( \beta \) and replace \( N' \) by \( N'-1 \) (where \( N' = \lceil \frac{N}{d} \rceil \)). We may then test the second largest ordinate. The major problem with this procedure is that our overall significance level will not be \( \alpha \) (in fact it will be \( > \alpha \)).
Suppose we have a time series and we assume it has a period of $T$ time units. A simple way for detecting this period $T$ was devised by Buys-Ballot in 1847 (see, for example Whittaker and Robinson (1924) or Buys-Ballot (1847)). Write out all the data in the time series in groups of $m$ ($m=2,3,...$)

\[
\begin{array}{cccc}
1 & 2 & 3 & \ldots & m \\
X_1 & X_2 & X_3 & \ldots & X_m \\
X_{m+1} & X_{m+2} & X_{m+3} & \ldots & X_{2m} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
X_{km-1} & X_{km+2} & X_{km+3} & \ldots & X_{km+m} \\
X_1 & X_2 & X_3 & \ldots & X_m \\
\end{array}
\]

Calculate the mean of each column (as above) and calculate the variance of these means. Compute the ratio $r$ or $r^2$ where

\[
r = \frac{\tau}{\sigma_m} = \frac{\text{std. dev. of means}}{\text{std. dev. of all the data}}
\]

and $\sigma_m$ = std. dev. of means

$\tau$ = std. dev. of all the data.

Whittaker and Robinson (1924) have shown that $r$ plotted against $m$ is very similar to the periodogram and has much the same properties.

Excess $X_i$'s are just discarded
APPENDIX A7: SAMPLING PROPERTIES OF SPECTRAL ESTIMATES

As in chapter four, define an estimate of the sdf \( h(w) \) to be of the form

\[
h(w) = \frac{1}{2\pi} \sum_{|t|<N} \lambda_t e^{-itw}
\]

where \( \lambda_t \) = lag window
\( c_t \) = sample acvf
and our sample estimate is based on a realization \( x_0, x_1, \ldots, x_{N-1} \) from a stationary (second-order) process \( \{X_t\} \).

Define

\[
\hat{\rho}_N(\theta) = \frac{1}{2\pi} \sum_{|t|<N} c_t e^{it\theta}
\]

= spectral window.

Assume \( \lambda_t = \delta_{-t} \), i.e. \( \{\lambda_t\} \) is an even function, thus \( \hat{\rho}_N(\theta) \) is a real-valued function of \( \theta \) and is continuous for all \( \theta \) (since it is a finite sum of cosine functions).

\[
\hat{\rho}_N(\theta) > 0 \quad \forall N, \theta \quad (\text{by a7.2})
\]

If we assume \( \lambda_0 = 1 \), then

\[
\int_{-\pi}^{\pi} \hat{\rho}_N(\theta) d\theta = 1
\]

Furthermore, assume \( \hat{\rho}_N(\theta) \) is such that

\[
\int_{-\pi}^{\pi} \hat{\rho}_N^2(\theta) d\theta < \infty \quad \text{for finite } N \text{ and }
\]

\[
\hat{\rho}_N(\theta) \to 0 \text{ uniformly as } N \to \infty \quad \text{for } |\theta| > \delta \quad (\delta > 0)
\]
Also note that
\[ \lim_{N \to \infty} \frac{\int_1^N t^2 \, dt}{L^2} = 0 \quad \text{as } N \to \infty \]  
(a7.7)

and
\[ \left( \int_1^N (N) \, dt \right)^2 = 0 \quad \text{as } N \to \infty \]  
(a7.8)

(by (a7.3), (a7.4) and (a7.5))

The above assumptions and notes make it easier to calculate
asymptotic statistical properties of $h(w)$, which are given here,
but with no details.

**Theorem A**

If $g_1(w)$ and $g_2(w)$ are 2 real-valued functions on $(-\infty, \infty)$, each
with a finite number of discontinuities (possibly zero) and if
both are absolutely integrable and square integrable

i.e.
\[ \int_{-\infty}^{\infty} |g_i(t)|^2 \, dt < \infty \quad i = 1, 2 \]

and
\[ \int_{-\infty}^{\infty} |g_i(t)|^2 \, dt \leq C \]

then if $X_t$ is a process of the form
\[ X_t = \sum_{k=1}^{\infty} a_k \omega_{tk} \quad \forall t \]

where $\omega_t$ is a white noise process with $E(a_k^2) = \mu$ and
\[ \sum_{k=1}^{\infty} |a_k| \mu^{k/2} < \infty \]

where $a_k$ is of order $|t|^{-k} (k > 1)$ and writing
\[ g_i(w) = I^*(w)dw \]
(w) as in (4.5)

and

\[ I_i^* = \int_{-\pi}^{\pi} g_i^*(w)h(w)dw \quad i = 1, 2 \]

then

(a) \( \lim_{N \to \infty} E(\beta_1^*) = \beta_1 \)

(b) \( \lim_{N \to \infty} N \text{Cov}(\beta_1^*, \beta_2^*) = e_{12}^2 - 4\pi \int_{-\pi}^{\pi} g_1^*(w)g_2^*(w)h^2(w)dw \)

where \( e = E(\xi_i^4) - 3 \)

and \( g^*_2(w) = \frac{1}{2}(g_2(w) + g_2(-w)) \)

(c) \( \lim_{N \to \infty} N \text{V}(\beta_1^*) = \sigma_1^2 e_{12}^2 - 4\pi \int_{-\pi}^{\pi} g_1^*(w)g_1^*(w)h^2(w)dw \quad i = 1, 2 \)

Proof: see, for example, Priestly (1981), p. 427.

Result 1

Replacing \( g_1(w) \) and \( g_2(w) \) by \( W_1(w - w) \) and \( W_2(w - w) \) (resp.), then provided

\[ x = a: Vt \text{as in the theorem, then} \]

\[ E(h(w)) = \int_{-\pi}^{\pi} h(\omega)W_1(w - \omega)d\omega = h^*(w) \text{ say} \quad (\text{a7.10}) \]

and

\[ E(I^*(w)) = \int_{-\pi}^{\pi} h(\omega)D_0(\omega - w)d\omega \quad (*\text{7.11}) \]

where

\[ D_0(\omega) = \frac{1}{2\pi} \frac{\sin^2(\omega/2)}{N\sin^2(\omega/2)} \]

provided \( h(w) \) has bounded first derivative (\( (\text{a7.10}) \) follows from theorem A and \( (\text{a7.11}) \) was shown by Fejcr (1910)).
Result 2

In fact result 1 can be extended so that

\[ \mathbb{E}(h(w)) = \int_{-\pi}^{\pi} h(\theta) \mathcal{W}_N(w - \theta) d\theta + O(\frac{1}{N}) \tag{a7.12} \]

Result 3

If we assume \( h(w) \) is continuous for all \( w \), then using (a7.1) and (a7.6), it may be shown that

\[ \lim_{N \to \infty} \mathbb{E}(h(w)) = h(w) \quad \forall w \tag{a7.13} \]

Result 4

By theorem A,

(a) \( N \mathbb{V}(h(w)) = e^h^*(w) 2 - 2 \int_{-\pi}^{\pi} h^*(\theta) \mathcal{W}_N(w-\theta) \mathcal{W}_N(w-\theta) d\theta \]

(b) \( \mathbb{Cov}(h(w_1), h(w_2)) = e^h(w_1)h(w_2) + 2 \int_{-\pi}^{\pi} h^*(\theta) \mathcal{W}_N(w_1-\theta) \mathcal{W}_N(w_2-\theta) d\theta \)

Result 5

As \( N \to \infty \), \( h(w) \) has the limiting form of a Dirac delta function. The first term in result 4(a) is of order 1 and so negligible when compared with the second term as \( N \to \infty \).

Now

\[ \mathcal{W}_N(w-\hat{w}) \to \text{Dir}(w-\hat{w}) \]

\[ \mathcal{W}_N(w-\hat{w}) \to \text{Dir}(w-\hat{w}) \]

(where Dir is the Dirac delta function)
\[ \int_{-\pi}^{\pi} h^2(\theta) W_N(w-\theta) W_N(w+\theta) d\theta = 0 \quad \text{as} \quad N \to \infty \]

In fact

\[ V(h(w)) = (1+\delta) \sum_{N} \int_{-\pi}^{\pi} h^2(\theta) W_N^2(w-\theta) d\theta \]

\[ = \begin{cases} 
1 & \text{if } w = 0 \text{ or } \tau \\
0 & \text{otherwise}
\end{cases} \]

But

\[ \int_{-\pi}^{\pi} h^2(\theta) W_N^2(w-\theta) d\theta = h^2(w) \sum_{N} W_N^2(w-\theta) d\theta \]

\[ = h^2(w) \sum_{N} w_N^2(\theta) d\theta \]

(1. e \( W_N(\theta) \) has period 2\( \pi \))

so

\[ V(h(w)) = (1+\delta) \sum_{N} h^2(w) \int_{-\pi}^{\pi} W_N^2(\theta) d\theta \]

However

\[ \sum_{N} h^2(w) \int_{-\pi}^{\pi} W_N^2(\theta) d\theta = \sum_{|\xi| \leq N} \frac{1}{\xi^2} \]

\[ \therefore V(h(w)) = (1+\delta) \sum_{N} h^2(w) \sum_{|\xi| \leq N} \frac{1}{\xi^2} \]

**Result 6**

The first term of result 4(b) is always of order 1 and the second term involves the integral of products of functions, so if \( w_1 \) and \( w_2 \) are fixed (and \( w_1 \neq w_2 \)), the second term tends to zero and

\[ \lim_{N \to \infty} \text{Cov}(h(w_1), h(w_2)) = 0 \quad \text{if} \quad w_1 \neq w_2 \]
Considering \( N \) to be large but finite, the first term of \( 4(b) \) is still of order \( 1 \), but the second term tends to zero if \( w_1 \) and \( w_2 \) are close, thus

\[
\text{Cov}(h(w_1), h(w_2)) = \frac{2N}{N} \int_{-\pi}^{\pi} \hat{h}(\xi) \hat{G}(\xi)^2 \hat{G}(w_1-w_2)^2 d\xi
\]

Result 7

Let

\[
b(w) = F(h(w)) - h(w)
\]

be bias in \( h(w) \) at \( w \)

Now

\[
E(h(w)) = \int_{-\pi}^{\pi} h(\xi) N(\xi, w) d\xi + O\left(\frac{\log N}{N}\right) \quad \text{(result 2)}
\]

so

\[
b(w) = \int_{-\pi}^{\pi} \left[ h(\xi) - h(w) \right] N(\xi, w) d\xi + O\left(\frac{\log N}{N}\right)
\]

Ignoring the second term,

\[
b(w) = \int_{-\pi}^{\pi} \left[ h(\xi) - h(w) \right] \frac{N(\xi, w)}{N} d\xi
\]

If \( h(w) \) is twice differentiable (with bounded second derivative) and for \( \beta \) small,

\[
\hat{h}(w) = h(w) - \beta h'(w) = \frac{1}{2} h''(w) + O(\beta^2)
\]

\[
b(w) = \frac{1}{2} \int_{-\pi}^{\pi} h''(\xi) \hat{G}(\xi) d\xi
\]
Result 8

$h(w)$ is asymptotically unbiased (result 3) so $h(w)$ is consistent if

$$\lim_{N \to \infty} \left( \frac{1}{N} \int_{-\pi}^{\pi} \frac{1}{N} \int_{-\pi}^{\pi} d\theta d\vartheta \right) = 0 \quad \text{(by result 5)}$$

i.e. if

$$\lim_{N \to \infty} \left( \frac{1}{N} \sum \frac{1}{N} \right) = 0$$

Result 9

(Proving $h(w)$ is not a consistent estimate of $\hat{\theta}_N(w)$)

$$h(w) = \int_{-\pi}^{\pi} I^*(w) \hat{\theta}_N(w-\vartheta) d\vartheta \quad \text{from section 4.1}$$

Suppose we approximate this integral by a sum over $j = 2^{-j/N}$

$$h(w) = \sum_{j} \hat{\theta}_N(w-w_j) I^*(w_j)$$

Suppose also that

$$x_t = \sum a_u z_{t-u} \quad \text{where } z_t \sim N(0, \sigma^2)$$

and $E(x_t x_t') = \sigma^2 I$ with $\sum \frac{a_u(a_u')}{u} = \sigma^2$ independent

i.e. suppose $x_t$ is a moving average process

Then

$$I^*_N(w) = \left| A(w) \right|^2 I^*(w)$$

where $\left| A(w) \right|^2 = \sum a_u^2 e^{-juw}$

Since the $\{z_t\}$ are uncorrelated, then

$$h(w) = \text{sdf of } \{z_t\}$$
thus \( h_x(w) = \frac{-2}{2\pi} |A(w)|^2 \)

hence \( I_x^*(w) = |A(w)|^{-2} I_x(w) \)

\[
I_x^*(w) = \frac{2\pi}{2} h_x(w) I_x^*(w)
\]

By the distribution of \( I_x(w) \), (asymptotically), the

\( I_x(w_j)/2\pi h_x(w_j) \) \( (j = 0, \ldots , \lfloor \frac{N}{2} \rfloor) \)

are independently distributed, and in fact

\[
I_x(w_j) = \begin{cases} 
4\pi h_x(w_j)^2 & j = 0 \text{ or } \lfloor \frac{N}{2} \rfloor \\
2\pi h_x(w_j)^2 & \text{otherwise}
\end{cases}
\]

thus

\[
E(I_x(w_j)) = 4\pi h_x(w_j)^2 \text{ for } j = 0 \text{ or } \lfloor \frac{N}{2} \rfloor
\]

\[
V(I_x(w_j)) = 16\pi^2 h_x(w_j)^2
\]

But \( I_x^*(w) = \frac{1}{4\pi} I_x(w) \)

so

\[
E(I_x^*(w_j)) = h_x(w_j)^2
\]

\[
V(I_x^*(w_j)) = h_x(w_j)^2
\]

\( j = 0 \text{ or } \lfloor \frac{N}{2} \rfloor \)

Thus \( I_x^*(w) \) is not a consistent estimate of \( h_x(w) \).

**Result 10**

Consider the case where \( \lambda_x \) is of the form

\[ \lambda_x = k(x) \]

where \( k(x) \) is independent of \( N \).

Then \( W_q(i) \) is termed a scale parameter window. Assume

1. \( k(x) \) is continuous
2. \( k(x) \) is an even function
3. \( k(0) = 1 \)
4. \( \int_{-\infty}^{\infty} k^2(x)dx = \)
If we make the above assumptions, then (a7.3) - (a7.8) are satisfied provided that

\[ \frac{M}{N} = 0 \quad \text{as} \quad M,N \to \infty \]

So

\[ \frac{1}{N} \sum_{x=1}^{M} k(x) \left( \frac{t}{x} \right) + \int_{-\infty}^{\infty} k^2(x) dx = -\infty \]

Instead of result 5, we have

(a) \( \lim_{N \to \infty} \frac{N}{M} \mathbb{V}(h(w)) = (1-\hat{h}(w)) \int_{-\infty}^{\infty} k^2(x) dx \)

(b) \( \lim_{N \to \infty} \frac{N}{M} \text{Cov}(h(w_1), h(w_2)) = 0 \quad \text{for} \quad w_1 \neq w_2 \)

(c) Replacing \( k \) by \( k(\frac{t}{N}) \) in \( h(w) \) and taking expectations gives

\[ b(w) = \frac{1}{2\pi} \sum_{|t| < N} \left[ k(\frac{t}{N}) \left( 1 - \frac{1}{N} \right) - 1 \right] \gamma(t) e^{-itw} \]

\[ = \frac{1}{2\pi} \sum_{|t| < N} \left[ k(\frac{t}{N}) - 1 \right] \gamma(t) e^{-itw} \]

\[ = \frac{1}{2\pi} \sum_{|t| < N} t \left( k(\frac{t}{N}) \gamma(t) e^{-itw} \right) \]

\[ = \frac{1}{2\pi} \sum_{|t| > N} (t) e^{-itw} \]

Let \( r \) be the largest integer \( \leq 0 \) such that

\[ k^{(r)} = \lim_{x \to 0} \frac{1}{x^r} \frac{k(x)}{x} \quad (r \leq 0 \text{ and } < 0) \]
Suppose \( \tau < r \) and \( N \to \infty \), then taking the limit as \( M \to \infty \) of \( b(w) \), results in the second and third terms in \( b(w) \) tending to zero (as \( O(M^{-r}) \)) uniformly in \( w \), whilst the first term is (asymptotically) \( -k(r)W^{-r} h(r)(w) \) where

\[
\lim_{N \to \infty} M b(w) = -k(r) h(r)(w)
\]

i.e \( b(w) = -M^{-r} k(r) h(r)(w) \) as \( N \to \infty \)

For further details of all these results see Priestley (1981)

Note: Motivation behind the technique of comparing lag windows by using negated derivatives

As in chapter 4 define

\[
h(w) = \text{spectral density function (sdf)}
\]

\[
h(w) = \frac{1}{2\pi} \sum_{t=-\infty}^{\infty} \gamma(t) \cos(tw)
\]

where \( \gamma(t) = \text{acvf at lag t} \)

Now \( h(w) \) may be estimated by either

\[
\hat{h}(w) = \frac{1}{2\pi} \sum_{t \in N} \lambda_{1,t} c_{t}^1 \cos(tw)
\]

or by

\[
\tilde{h}(w) = \frac{1}{2\pi} \sum_{t \in N} \lambda_{2,t} c_{t}^2 \cos(tw)
\]

where
\[ \lambda_{i,t} = \text{lag window} \quad (i=1,2) \]

\[ s^* = (\text{biased}) \text{ estimate of } \gamma(t) \text{ (see section 2.4)} \]

\[ c_t = (\text{unbiased}) \text{ estimate of } \gamma(t) \text{ (see section 2.4)} \]

\[ N = \text{size of the observed time-series} \]

Define

\[ k_{i}(M) = \lambda_{i,t} \quad \forall t \quad (M = \text{truncation point}) \]

thus

\[ k_{i}(0) = 1 = \lambda_{i,0} \]

\[ k_{i}(-\beta) = k_{i}(\beta) \quad 0 < \beta < 1 \]

\[ k_{i}(\beta) = 0 \quad \beta > 1 \quad (\text{i.e. } t > M) \]

[Note that

\[ h(\beta) = h(\beta) \text{ iff} \]

\[ \lambda_{2,t} = \left(1 - \frac{i}{N}\right) \lambda_{1,t} \]

Define another estimate of the sdf by

\[ S_t(w) = \frac{1}{2\pi} c_0 + \frac{1}{2} \sum_{u=1}^{M} c_u \cos(uw) \quad (t > 1) \]

with \( S_0(w) = c_0 \).

(Note that if \( t = N-1 \), \( S_{N-1}(w) \) is very similar to the periodogram).

Since

\[ \frac{1}{2} c_t \cos(tw) = S_t(w) - S_{t-1}(w) \quad (t > 0) \]

then

\[ h(w) = \frac{1}{2\pi} c_0 + \frac{1}{2} \sum_{t=1}^{M} c_t \cos(tw) \]

\[ = \frac{1}{2\pi} S_0(w) + \sum_{t=1}^{M} \left( S_t(w) - S_{t-1}(w) \right) \]

\[ = \sum_{t=0}^{M-1} \pi_j w = \pi_{t+1} S_t(w) + \pi_y S_M(w) \]
\[
\begin{align*}
&= \frac{\delta}{M-1} \left[ k_2 \left( \frac{t-1}{M} \right) - k_2 \left( \frac{t-1}{M} \right) \right] S_t(w) - k_2(1) S_M(w)
\end{align*}
\]

From the mean value theorem, for some \( \in (0,1) \)

\[
k_2 \left( \frac{t-1}{M} \right) - k_2 \left( \frac{t-1}{M} \right) = \frac{1}{M} k_2' \left( \frac{t-1}{M} \right)
\]

if \( M \) is not too small.

Thus the weight applied to \( S_t(w) \) in \( h(\cdot) \) is approximately proportional to \( k_2' \left( \frac{t}{M} \right) \).

At those values of \( t \) for which \( S_t(\cdot) \) is likely to be a good estimate of \( h(\cdot) \), the negated derivative, \( -k_2' \left( \frac{t}{M} \right) \), should be (comparatively) large, while for other values it should be small.

So an indicator of the properties of the spectrum estimate \( h(\cdot) \) (or \( h(\cdot) \)) using \( k_{2,t} \) (or \( k_{1,t} \)), is the (negated) derivative of \( k_{n,\cdot} \) (or \( k_{1,\cdot} \)).

Neave (1972) states that if the spectrum is not too complicated and has no excessively high and narrow peaks, then the weighting factor (i.e. \( -k_2' \left( \frac{t}{M} \right) \)) should be small for \( t \) close to zero (since then \( S_t(\cdot) \) has large bias) and rise to a maximum somewhere near \( t = 20 \). For \( t \) large, \( S_t(\cdot) \) is also a bad estimate since it has a large variance - see Neave (1972).
From the mean value theorem, for some \(0 < \theta < 1\)
\[
\xi = \sum_{i=0}^{\frac{M-1}{2}} \left[ k_2\left(\frac{\xi + i}{M}\right) - k_2\left(\frac{\xi - i}{M}\right) \right] \xi_t(w) + k_2(1) \xi_w(w)
\]

From the mean value theorem, for some \(0 < \theta < (0,1)\)
\[
k_2\left(\frac{\xi + 1}{M}\right) - k_2\left(\frac{\xi}{M}\right) = \frac{1}{M} k_2\left(\frac{\xi + 1}{M}\right) = \frac{1}{M} k_2\left(\frac{\xi}{M}\right)
\]

if \(\xi\) is not too small.

Thus the weight applied to \(S_t(w)\) in \(\hat{h}(\cdot)\) is approximately proportional to \(-k_2(\frac{\xi}{M})\).

At those values of \(t\) for which \(S_t(\cdot)\) is likely to be a good estimate of \(h(\cdot)\), the negated derivative, \(-k_2(\frac{\xi}{M})\), should be (comparatively) large, while for other values it should be small.

So an indicator of the properties of the spectrum estimate \(\hat{h}(\cdot)\) (or \(h(\cdot)\)) using \(\xi\) (or \(\xi\)) is the (negated) derivative of \(k_2(\cdot)\) (or \(k_1(\cdot)\)).

Neave (1972) states that if the spectrum is not too complicated and has no excessively high and narrow peaks, then the weighting factor (i.e., \(-k_1(\frac{\xi}{M})\)) should be small for \(t\) close to zero (since then \(\hat{S}_t(\cdot)\) has large bias) and rise to a maximum somewhere near \(t = 20\). (For \(t\) large, \(\hat{S}_t(\cdot)\) is also a bad estimate since it has a large variance - see Neave (1972)).
APPENDIX A8: APPROXIMATE VARIANCE IN SPECTRUM ESTIMATES

\[ I^*(w) = \frac{1}{2\pi} \sum_{t=1}^{N} e^{-itw} = \text{periodogram} \]

\[ h(w) = \text{estimate of sdf } h(w) \]

\[ = \int_{-\pi}^{\pi} I^*(\theta) \mathcal{W}_N(w-\theta) d\theta \]

where \( \mathcal{W}_N(w-\theta) = \frac{1}{2\pi} e^{-it(w-\theta)} \)

\[ = \text{spectral window} \]

If the time series \( X_t \) is Gaussian, then the periodogram ordinates \( I^*(w_j) \) \( (w_j = 2\pi j/N, \quad j = 1, \ldots, \lfloor N/2 \rfloor) \) are independently distributed as \( \mathcal{N} \) (if \( j = 0 \) and \( j = \lfloor N/2 \rfloor \))

As \( N \to \infty \)

(1) \( E(I^*(w)) = n(w) \)

so \( E(h(w)) = \int_{-\pi}^{\pi} h(\theta) \mathcal{W}_N(w-\theta) d\theta \)

(since \( E(h(\omega)) = E \left( \int_{-\pi}^{\pi} I^*(\theta) \mathcal{W}_N(w-\theta) d\theta \right) \)

\[ = \int_{-\pi}^{\pi} E(I^*(\theta)) \mathcal{W}_N(w-\theta) d\theta \]

\[ = \int_{-\pi}^{\pi} h(\theta) \mathcal{W}_N(w-\theta) d\theta \]

(11) \( V(h(w)) = \frac{2}{N} \int_{-\pi}^{\pi} h^2(\theta) \mathcal{W}_N^2(w-\theta) d\theta \) \( (w \neq 0, \pm \pi) \)

\[ = \frac{2}{N} h^2(w) \int_{-\pi}^{\pi} \mathcal{W}_N^2(w-\theta) d\theta \quad (w = 0, \pm \pi) \]

(since \( h(\theta) \) is continuous and for large \( N \), \( \mathcal{W}_N(w-\theta) \) is highly concentrated about \( \theta = w - \omega \); see, for example, Priestley (1981))
If we approximate $\hat{h}(w) = \int_{-\pi}^{\pi} I^*(\theta) W_N(w-\theta) d\theta$

by a discrete sum over the ordinates $\frac{2\pi}{N}$, then

$$\hat{h}(w) = \left( \frac{2\pi}{N} \right) \sum_{j=1}^{N} W_N(w-w_j) I^*(w_j)$$

and hence $\hat{h}(w)$ is (approximately) a weighted sum of $\chi^2$ r.v. and so it seems quite reasonable to approximate its distribution by a $\chi^2$ distribution where

$$f = \frac{N}{\int_{-\pi}^{\pi} W_N^2(w-\theta) d\theta} = \frac{2E(h(w))}{V(h(w))}$$

The (approximate) variances of some spectral estimates are given on the next page in the form

$$\frac{\chi^2(h(w))}{h^2(w)} = \frac{N}{M} = \chi^2(w = 0, -)$$

(Since $2E(h(w)) = \int_{-\pi}^{\pi} I^2(\theta) d\theta = \frac{2}{\pi}$)

$$\Rightarrow h^2(w) = \frac{2}{\pi N} h(w)$$

and thus we have an alternative method of calculating the approximate variance.

The bias of these windows may be obtained from, for example, Priestley (1981), pg. 163.

Notes:

(i) For the case $w = 0$ or $\pi$, each of the above $V^*$ must be doubled.

(ii) Each of the above $V^*$ was calculated by considering the windows as scale parameter windows i.e. writing

$$V = \frac{1}{2} \sum_{t=-[N]}^{[N]} k^2(x) dx$$

where $M = \text{truncation point}$. Since

$$\lim_{N \to \infty} \frac{1}{N} \sum_{t=-[N]}^{[N]} k^2(x) dx = \frac{\int_{-\infty}^{\infty} k^2(x) dx}{\int_{-\pi}^{\pi} h^2(w) dx}$$

and hence for each window only $\int k^2(x) dx$ need be calculated.
(iii) Choice of window is not only dependent on the (asymptotic) variance but also on the (asymptotic) bias. So before defining any of the above windows as best, the bias for each window must be calculated and then some technique decided upon in order to maximize (or minimize $P_1(w)$ or $P_2(w)$) (as defined in section 5.3).
APPENDIX A9 : OBTAINING INITIAL ESTIMATES IN AN ARMA PROCESS

Suppose \( \{X_t\} \) is zero-mean (second order) stationary and follows an ARMA \((p,q)\) process, i.e.,

\[
\phi(B)X_t = \theta(B) \varepsilon_t
\]

where \( \phi(B) = 1 - \phi_1 B - \cdots - \phi_p B^p \)

\( \theta(B) = 1 - \theta_1 B - \cdots - \theta_q B^q \)

\( \{\varepsilon_t\} = \text{white noise} \)

Box and Jenkins (1976) have suggested the following procedure for calculating initial estimates in an ARMA \((p,q)\) model.

(a) Calculate \( \hat{\phi}_1, \hat{\phi}_2, \ldots, \hat{\phi}_p \) from \( c_{q-p+1}, \ldots, c_{q+p} \) by using the Y-W equations. (See equation (6.16a) to see why \( c_{0}, \ldots, c_{q+1} \) are not used)

(b) Find the autocovariances \((q + 1\) of them) of the new series \( x_t^* = x_t - \bar{x}_t \)

(c) Calculate \( \hat{\beta}_1, \hat{\beta}_2, \ldots, \hat{\beta}_q \) by using the following quadratically convergent procedure

(i) Denote \( \hat{\gamma}_t = (\hat{\gamma}_0, \hat{\gamma}_1, \ldots, \hat{\gamma}_q) \) and let

\[
\hat{\beta}_j = -\frac{\hat{\gamma}_j}{\hat{\gamma}_0} \quad j = 1, \ldots, q \quad \gamma_0 = \sigma_a^2
\]

(ii) Let \( \hat{\beta}^{(i)} \) denote the \( \hat{\beta} \) obtained at iteration \( i \) then

\[
\hat{\beta}^{(i+1)} = \frac{\hat{\beta}^{(i)} + f'(\hat{\beta}^{(i)})}{1 - f''(\hat{\beta}^{(i)})}
\]

where \( f' = (f_0, f_1, \ldots, f_q) \)

Strictly speaking, the Yule-Walker equations were defined i.t.o. the acv. However, multiplying the Y-W equations (through-out) by \( \gamma(0) \) yields a set of equations i.t.o. the acv.
with

\[ f_j = \sum_{i=0}^{q-j} \tau_i \delta_{i+j} = n_j \]

and \( c''_j \) = \( j^{th} \) acv of \( y_t \)

and

\[
T = \begin{pmatrix}
\tau_0 & 1 & \cdots & \tau_q \\
0 & \tau_2 & \cdots & 0 \\
& \vdots & \ddots & \vdots \\
0 & \cdots & 0 & \tau_q \\
\end{pmatrix}
+ \begin{pmatrix}
\tau_0 & \tau_1 & \cdots & \tau_q \\
0 & \tau_0 & \cdots & \tau_{q-1} \\
& \vdots & \ddots & \vdots \\
0 & \cdots & 0 & \tau_0 \\
\end{pmatrix}
\]

For more details, see Box and Jenkins (1976) pg. 201
APPENDIX A10 : A RECURSIVE METHOD FOR CALCULATING ESTIMATES OF AR PARAMETERS

Here we will show how Yule-Walker estimates for the parameters of an AR(p-1) process may be obtained from the estimates of an AR(p) process, and used to approximate the pacrf.

\[ r_j = \phi_k r_{j-1} + \ldots + \phi_{(k-1)} r_{j-(k-1)} + \phi_k r_{j-k} \quad (\forall j \geq p) \]

(by the Yule-Walker equations - see section 6.3.1 and in particular equation (6.10)) where \( \phi_i \) (i=1,...,k) refer to the coefficients of an AR(k) process

In particular, when k = 2

\[ r_2 = \phi_1 r_1 + \phi_2 r_2 \]
\[ r_1 = \phi_1 r_1 + \phi_2 r_2 \]

and when k = 3

\[ r_3 = \phi_1 r_2 + \phi_2 r_1 + \phi_3 r_3 \]
\[ r_2 = \phi_1 r_2 + \phi_2 r_1 + \phi_3 r_2 \]
\[ r_1 = \phi_1 r_1 + \phi_2 r_2 + \phi_3 r_3 \]

It may be shown, by writing (a10.2) in matrix form and solving for \( \phi_31 \) and \( \phi_32 \), that

\[ \phi_31 = \phi_1 - \phi_3 \phi_22 \]
\[ \phi_32 = \phi_2 - \phi_3 \phi_21 \]

Substituting these two equations into (a10.1) gives

\[ \phi_3 = \frac{r_3 - \phi_1 r_2 - \phi_2 r_1}{1 - \phi_1 r_1 - \phi_2 r_2} \]
In general, (Durban (1960)) it may be shown that

\[ r_{p+1,j} - \sum_{j=1}^{p} r_{p+1,p+1-j} = \sum_{j=1}^{p} \hat{p}_{j} \hat{p}_{p+1-j} \]

Also see Box and Jenkins (1976) pg. 92
APPENDIX A11: PARAMETER ESTIMATES AND PROPERTIES OF SPECIFIC BJ MODELS

AR(1)

stationarity condition
\[ |\phi_1| < 1 \]

\[ s_1 = r_1 \]

behaviour of acrf

decays slowly

behaviour of pacrf

only \( s_{11} \) nonzero

\[ s_a^2 = \gamma(0)(1 - \phi_1 \delta(1)) \]

AR(2)

stationarity condition
\[ |\phi_1| < 1 \]
\[ |\phi_2| < 1 \]
\[ |\phi_1 \phi_2| < 1 \]

invertibility condition
\[ \phi(k) = \phi_1 \delta(k-1) + \phi_2 \delta(k-2) \quad k > 0 \]

acrf
\[ \sigma_x^2 = \frac{\sigma_a^2}{\delta_1 \delta_2} (1 - \frac{1}{\phi_1 \phi_2 \delta_1 \delta_2} \delta_1 \delta_2 - \frac{1}{\delta_1 \delta_2}) \]

variance
\[ \sigma_x^2 = \frac{\sigma_a^2}{\delta_1 \delta_2} (1 - \frac{1}{\phi_1 \phi_2 \delta_1 \delta_2}) \]

spectrum
\[ h(w) = \frac{\sigma_a^2}{1 + \frac{1}{\delta_1 \delta_2} \delta_1 \delta_2 (1 - \frac{1}{\phi_1 \phi_2 \delta_1 \delta_2} \delta_1 \delta_2) \cos(w) - 2\delta_1 \delta_2 \cos(2w)} \]

\[ s_1 = \frac{r_1 - \phi_2}{1 - \phi_1} \]
\[ s_2 = \frac{r_2 - \phi_1}{1 - \phi_1} \]
\[ s_1 = \frac{r_1}{1 - \phi_1} \]
Behavior of acrf

A mix of exponentials or damped sine waves

Behavior of pacrf

Only $\beta_{11}$ and $\beta_{22}$ nonzero

$\sigma^2_a = \sigma^2_a(1 - \phi_1^2(1) - \phi_2^2(2))$

MA(1)

Stationarity condition

$|\beta_1| < 1$

Invertibility condition

$c(1) = -\beta_1/(1 + \beta_1^2)$

$\rho(k) = 0 \quad k > 1$

Variance

$\sigma^2 = (1 + \beta_1^2)\sigma^2_a$

Spectrum

$h(w) = \frac{\sigma^2_a(1 - \beta_1^2 \cos(w))}{1 - \beta_1^2}$

$r_1' = \frac{1}{(1 + \beta_1^2)}$

(And solve for $r_1'$)

Only $c(1)$ nonzero

Behaviour of acrf

Exponential dominates the decay

$\sigma^2_a = \sigma^2_a/(1 + \beta_1^2)$

MA(2)

Stationarity condition

$\beta_1 + \beta_2 < 1$

$\beta_2 - \beta_1 < 1$

$-1 < \beta_2 < 1$

Acfr

(1) = $-\beta_1/(1 - \beta_2)/(1 + \beta_1^2\beta_2^2)$

(2) = $-\beta_2/(1 + \beta_1^2\beta_2^2)$

$\rho(k) = 0 \quad k > 2$

Variance

$\sigma^2 = \sigma^2_a/(1 + \beta_1^2\beta_2^2)$
All.3

spectrum

\[ h(w) = 2\sigma_\alpha^2 \left[ (1-\hat{\phi}_1,\hat{\theta}_1) - \frac{2\hat{\theta}_1,\hat{\phi}_1,\phi_1 \cos(w)}{2(1-\hat{\phi}_1,\hat{\theta}_1)} \right] \]

\[ r_1^1 = \frac{1-\hat{\phi}_1,\hat{\theta}_1}{(1-\hat{\phi}_1,\hat{\theta}_1)} \]
\[ r_2^1 = \frac{1-\hat{\phi}_1,\hat{\theta}_1}{(1-\hat{\phi}_1,\hat{\theta}_1)} \]

(Solve for \( \hat{\theta}_1 \) and \( \hat{\phi}_1 \))

behaviour of acrf

only 0(1) and \( \omega(2) \) nonzero

behaviour of pacrf

mix of exponentials and sine waves

\[ \sigma_\alpha^2 = \frac{2\hat{\theta}_1,\hat{\phi}_1,\phi_1}{(1-\hat{\phi}_1,\hat{\theta}_1)} \]

ARMA (1, 1)

stationarity condition

\[ |\hat{\phi}_1| < 1 \]

invertibility condition

\[ |\hat{\theta}_1| < 1 \]

acvf

\[ \gamma(k) = \frac{\sigma_\alpha^2}{(1-\hat{\phi}_1,\hat{\theta}_1)} \]

\[ \sigma_\alpha^2 = \frac{1}{(1-\hat{\phi}_1,\hat{\theta}_1)} \sigma_\alpha^2 \]

variance

\[ \sigma_\alpha^2 = \frac{1}{(1-\hat{\phi}_1,\hat{\theta}_1)} \sigma_\alpha^2 \]

\[ h(w) = \frac{\gamma(w)}{2(1-\hat{\phi}_1,\hat{\theta}_1) \cos(w)} \]

\[ r_1^a = \frac{1}{1 + \frac{\sigma_\alpha^2}{2(1-\hat{\phi}_1,\hat{\theta}_1)}} \]

\[ r_2^a = \frac{1}{1 + \frac{\sigma_\alpha^2}{2(1-\hat{\phi}_1,\hat{\theta}_1)}} \]

(Solve for \( \hat{\theta}_1 \) and \( \hat{\phi}_1 \))

behaviour of acrf

decays exponentially

behaviour of pacrf
dominated by an exponential

\[ \sigma_\alpha^2 = \frac{\sigma_\alpha^2}{1 + \frac{\sigma_\alpha^2}{2(1-\hat{\phi}_1,\hat{\theta}_1)}} \]
Notes

(i) The Yule-Walker equations may be expressed in the form

\[ \hat{\rho} = \rho^{-1} \hat{\omega} \]

where \( \hat{\rho} = (\rho(1), \ldots, \rho(p)) \)

and

\[ P = \begin{bmatrix}
1 & \rho(1) & \cdots & \rho(p-1) \\
\rho(1) & 1 & \cdots & \rho(p-2) \\
\vdots & \vdots & \ddots & \vdots \\
\rho(p-1) & \cdots & 1 & 1
\end{bmatrix} \]

with \( \hat{\omega} = (\hat{\omega}_1, \hat{\omega}_2, \ldots, \hat{\omega}_p) \)

So

\[ \hat{\omega} = \hat{\omega}^T \]

and

\[ V(\hat{\omega}) = \frac{1}{N} \hat{\omega}^2 \hat{\omega}^{-1} = \frac{1}{N} (1 - \hat{\omega}^2) P^{-1} \]

since

\[ \hat{\omega}^2 = \gamma(0) (1 - \hat{\omega}^2) \]

where \( \gamma \) and \( P \) are the acv and acr matrices of an AR(p) process.

(ii) In particular, if we have an AR(2) process then

\[ V(\hat{\omega}_1, \hat{\omega}_2) = \frac{1}{N} \begin{bmatrix}
1 - \hat{\omega}_2^2 & -\frac{1}{2} (1 + \hat{\omega}_2^2) \\
\frac{1}{2} (1 + \hat{\omega}_2^2) & 1 - \hat{\omega}_2^2
\end{bmatrix} \]

(iii) For an MA(2) process

\[ V(\hat{\omega}_1, \hat{\omega}_2) = \frac{1}{N} \begin{bmatrix}
1 - \hat{\omega}_2^2 & -\frac{1}{2} (1 + \hat{\omega}_2^2) \\
\frac{1}{2} (1 + \hat{\omega}_2^2) & 1 - \hat{\omega}_2^2
\end{bmatrix} \]

(iv) For an ARMA(1,1) process

\[ V(\hat{\omega}, \hat{\omega}) = \frac{1}{N} \begin{bmatrix}
(1 - \hat{\omega}^2)(1 - \hat{\omega}) & (1 - \hat{\omega}^2)(1 - \hat{\omega}) \\
(1 - \hat{\omega}^2)(1 - \hat{\omega}) & (1 - \hat{\omega}^2)(1 - \hat{\omega})
\end{bmatrix} \]

(See Box and Jenkins (1976))
APPENDIX A12. ESTIMATION OF THE IACRF AND THE ASYMPTOTIC BEHAVIOUR OF THE IACR®

ESTIMATION OF THE IACRF

There are two techniques for calculating estimates for the iacrf - either by using the inverse model, or by using the periodogram estimate. The former is just like the procedures discussed in the For-Jenkins modelling sections (i.e. chapter six).

The latter is as follows.

(i) Suppose we have \( x_0, x_1, \ldots, x_{N-1} \)

(ii) Define the periodogram as in earlier chapters i.e.

\[
I(w) = \frac{1}{2N} \sum_{t=0}^{N-1} x_t e^{-itw}
\]

(and w.l.o.g assume \( E(x_t) = 0 \) \( \forall t \))

(iii) An estimate of the sdf is given by

\[
h(w) = \frac{1}{M} \sum_{j=1}^{M} S_j(w)
\]

(see Bloomfield (1976), pg 163 - all that we do here is divide the data into \( M \) segments each of length \( k \) say (where \( N = kM \)) and let \( S_j(w) \) be the periodogram of the \( j^{th} \) segment).

Any other estimate of the spectrum may be used.

(iv) Define the 'inverse' spectral density function by

\[
h_i(w) = 1/h(w)
\]

(iv) \( h_i(w) = 1/h(w) \)

Here \( x_0, \ldots, x_{N-1} \) is used instead of \( \{x_1, \ldots, x_N\} \) for notational convenience.
(v) The iacv $\gamma(k)$ are estimated by

$$\gamma(k) = \int_{-\pi}^{\pi} h(\omega) e^{i k \omega} d\omega$$

(see Cleveland (1972))

Chatfield (1979) has also proposed a technique for estimating the iacr and this involves fitting a large order AR process to the data i.e.

$$\chi_t = a_t + \sum_{i=1}^{v} \rho_i \chi_{t-i}$$

$$\therefore \rho(k) = \rho_k$$

$$= \frac{\sum_{i=1}^{v-k} \rho_{i-k} \rho_i}{1 + \sum_{i=1}^{v} \rho_i}$$

(which is the form of $C(k)$ for an MA(v) process).

Hipel et al (1977) suggest choosing about four values of $v$ between 10 and 30 (where $v \approx \frac{N}{2}$) and then using the 'most representative' graph.

2 THE ASYMPTOTIC DISTRIBUTION OF THE IACR

Suppose $\{X_t\}$ is zero-mean stationary with acvgf and iacvgf $\Phi(z)$ and $\Gamma(z)$ resp. Let the realization of the process be $x_0, x_1, \ldots, x_N$.

Then

$$\sqrt{N} (r_k - \gamma(k)) \overset{d}{\sim} \text{Normal (0, cov)}$$

where

$$\text{cov} = N(\gamma_k)$$

$$= \sum_{m=-\infty}^{\infty} \gamma(m)^2 (m+k) (m-k) + \sum_{k \neq m} \gamma(m) \gamma(k) (m-k)$$

(See appendix A3, (a3.3))
Now suppose

\[(B) x_t = 0(B) a_t \quad \forall t\]

then

\[h_X(x) = \text{pdf of } \{x_t\}\]

\[= \frac{a}{2\pi} \sum_{j=1}^{2^n} \frac{1 - \frac{a}{2^n} e^{-1jw}}{1 - \frac{a}{2^n} \theta e^{-1jw}}\]

by (6.21) \hspace{1cm} (a12.1)

and

\[h_1(w) = 1/h(w)\]

\[h_1(w) = \frac{2\pi}{2^n} \sum_{j=1}^{2^n} \frac{1 - \frac{a}{2^n} e^{-1jw}}{1 - \frac{a}{2^n} \theta e^{-1jw}}\]

\[\Rightarrow \text{so}\]

\[I(k) = \int_{-\pi}^{\pi} h_1(w) e^{ikw} \, dw\]

\[= \frac{2^n}{2^n} \int_{-\pi}^{\pi} \frac{1 - \frac{a}{2^n} \theta e^{-1jw}}{1 - \frac{a}{2^n} \theta e^{-1jw}} e^{ikw} \, dw\]

\[= \frac{2\pi}{(2^n)^2} G(w) \text{ sny}\]
But $G(w) = h(w)$

where $h(w)$ is the sdf of the process $\{Y_t\}$ where

$h(B)y_t = \vartheta(B)y_t$, i.e. an ARMA $(q,p)$ process.

Alternatively

$\psi(B)x_t = \vartheta(B)a_t \quad \forall t$

then write

$x_t = \alpha(B)a_t \quad \forall t$

where $\alpha(B) = \psi^{-1}(B)\vartheta(B)$

and define

$\Gamma_1(Z) = \text{acvgf of } \{X_t\}$

$= \varphi(Z)\varphi(Z^{-1})$ (see section 6.6)

If

$\psi(B)x_t = \psi(B)a_t \quad \forall t$

then

$x_t = \psi^{-1}(B)\varphi(B)c_t$

$= \psi^{-1}(B)c_t$

since $\psi^{-1}(B) = \psi(B)\psi^{-1}(B)$

So

$\Gamma_2(Z) = \varphi^{-1}(Z)\psi^{-1}(Z^{-1})$

But $\Gamma_1(Z)^{-1}(Z) = 1$ (by section 7.2.1)

$\Gamma_1(Z) = 1/\Gamma_1(Z)$

$= \varphi^{-1}(Z)^{-1} \psi^{-1}(Z) \psi^{-1}(Z^{-1})$

$= \Gamma_2(Z)(c_\psi)^2/c_\psi^2$

$\Gamma_2(Z) \Gamma_1(Z) = \varphi^{-1}(Z)$ say

i.e. $\Gamma_1(Z) = \Gamma_2(Z)$ if $c_\psi^2 = 1$
Similarly

\[ p_1 Z = p_2 Z \]

and \( p_1 Z = p_1 Z \)

Getting back to the original argument,

if \( \tilde{N} (r_k - Z(k)) \neq N(O, cov) \)

then surely

\( \tilde{N} (r_i - Z(k)) \neq N(O, cov) \)

Bhansali (1980) has shown that, asymptotically, the sampling distribution of the iscr, from an ARMA(p,q) process, is the same as that of the acr from an ARMA(q,p) process. (Also see Hosking (1980))
APPENDIX A13: THE DISTRIBUTION OF RESIDUAL AUTOCORRELATIONS

1. Consider

\[ \Phi(B)x_t = \theta(B)a_t \]

where \( \{X_t\} \) is a zero-mean stationary process.

Define

\[ r_{a,k} = \text{estimated acr of the residuals } a_t, \text{ at lag } k \]

\[ r_{a,k} = \frac{\sum_{t=k}^{N} a_t a_{t-k}}{\sum_{t=k}^{N} a_t^2} \]

\[ t = 0, \ldots, N-1 \tag{a13.1} \]

Now

\[ V(r_{a,k}) = \frac{N-k}{N(N+2)} \] (Anderson (1942) or Priestley (1981), pg. 339)

so if \( N \) is large

\[ \frac{N}{N+2} \sum_{k=1}^{N} \frac{1}{N-k} r_{a,k}^2 \approx \frac{2}{N} \] \[ \tag{a13.2} \]

assuming the \( r_{a,k}^2 \) are independent for different \( k \)

(since \( r_{a,k}^2 \approx N(0, \frac{N-k}{N(N+2)})^2 \) wk (Anderson (1942))

2. Let \( \hat{\beta} = (\hat{\beta}, \hat{\gamma}) \)

then

\[ \frac{1}{\hat{\beta}} \sim N(\hat{\beta}; I^{-1}/N) \]

where

\[ I = \begin{pmatrix} \sigma_v (1-j) & \sigma_{v} (1-j) b \\ \sigma_{v} (1-j) & \sigma_{v} (1-j) q \end{pmatrix} \]
and

\[ \Phi(B)v_t = a_t \]
\[ \Theta(B)u_t = a_t \]

\[ \gamma_{vv}(k) = E(v_t v_{t-k}) \]
\[ \gamma_{uu}(k) = E(u_t u_{t-k}) \]
\[ \gamma_{vu}(k) = E(v_t u_{t-k}) \]
\[ \gamma_{uv}(k) = \gamma_{vu}(-k) \]

(see Hannan (1970))

and

\[ v_{t-1} = \beta_1 v_t / \beta_1 \]
\[ u_{t-1} = \beta_1 v_t / \beta_1 \]

where \( a_t \) are the residuals obtained by replacing \( \beta \) with a known \( \beta \).

Hannan (1970) has shown that the large sample distribution of \( e = (e_{a,1}', ..., e_{a,m}') \) is normal with mean 0 and covariance matrix

\[ (1 - X^{-1}X')/N \]

as on the previous page

\( L = m \times m \) identity matrix

\[ X = \begin{pmatrix} 1 & -1 & \cdots & -1 \\ p & p & \cdots & p \\ q & q & \cdots & q \end{pmatrix} \]

(a partitioned matrix, with each partition showing its \( ij \) element)

where \( e_{a,j} \) and \( e_{a,j}^* \) are defined by

\[ L(B) = \sum_{j=0}^{L} e_{a,j} B^j \]

and

\[ L(B) = \sum_{j=0}^{L} e_{a,j}^* B^j \]

and \( e_{a,j} = 0 \) if \( j = 0 \).

(see McLeod (1978))
Invariably in the section on Box-Jenkins models, when finding the asymptotic distribution of $a_t$, residual $a_t$ etc, the $a_t$ (white noise) in the model

$$\phi(B)x_t = \psi(B)a_t$$

have been assumed to be independently distributed $N(0, \sigma^2)$. Davies, Spedding and Watson (1980) considered the case where $a_t$ is a zero-mean white noise process with variance $\sigma^2$, but with nonzero moment coefficient of skewness $\gamma_1(a)$ and moment coefficient of kurtosis $\gamma_2(a) = 3$.

Since any stationary ARMA process can be written i.e. an MA(\infty) process i.e.

$$x_t = \alpha(B)a_t$$

where

$$\psi(B) = 1 + B + \ldots$$

and $\phi(B)x_t = \psi(B)$

then

$$\gamma_1(x) = \frac{E(x^3_t)}{\left\{E(x^2_t)\right\}^{3/2}} = \frac{\sum_{j=1}^{\infty} \gamma_1(x)}{\sum_{j=0}^{\infty} \sigma^2}$$

$$\gamma_2(x) = \frac{E(x^4_t)}{\left\{E(x^2_t)\right\}^2} = \frac{\sum_{j=1}^{\infty} \gamma_2(x)}{\sum_{j=0}^{\infty} \sigma^2}$$

Davies, Watson and Spedding (1980) claim that usually only $\gamma_1$ and $\gamma_2$ are required (provided $p,q \ll 2$).
(A14.1) and (A14.2) can be used to approximate the appropriate skewness and kurtosis that need be imposed on the noise process \( \{a_t\} \) to generate \( \{X_t\} \) with given skewness and kurtosis.

[Also see Lomnicki (1961), Gabr and Subba Rao (1981), Subba Rao and Gabr (1981)]
APPENDIX A15 : ESTIMATING THE ORDER OF AR AND MA MODELS - THE MAX
$\chi^2$ METHOD

McClave (1975, 1978, 1978a) has developed a technique for determining the order of AR and MA models. Only the method for AR models will be given here since that of MA models follows from the AR procedure.

Suppose \( X_t \) is stationary (AR(p) process i.e.),
\[
x_t = \phi_1 x_{t-1} + \ldots + \phi_p x_{t-p} + a_t \quad \forall t
\]
where \( (a_t) \) is a zero-mean white noise process with variance \( \sigma^2 \).

If we have an AR(10), say, model, it is feasible that some subsets of the AR coefficients may provide models that fit equally well
\[
x_t = \phi'_1 x_{t-1} + \ldots + \phi'_5 x_{t-5} + a_t
\]
(analogous to subset regression models).

A general subset model will be denoted \( X_{\text{max}} \) with lags \( \{j_1, j_2, \ldots, j_g\} \) (where \( j_g = p \)) - so the model in our example is an AR model of order 3 max 10 with lags \( \{1,5,10\} \).

If \( \pi \) is the parameter set for the 'full' AR(p) model, then we may write the subset parameter vector \( \hat{\pi} \) as the union of two disjoint sets namely
\[
\hat{\pi} = \hat{\pi}_1 \cup \hat{\pi}_2
\]
where
\[
\hat{\pi}_1 = \{\phi_1, \phi_2, \ldots, \phi_p\}
\]
and
\[
\hat{\pi}_2 = \{\phi'_1, \phi'_2, \ldots, \phi'_5\}
\]

Note that \( \hat{\pi}_1 \) must be 'known' before \( \hat{\pi}_2 \).
Consider a realization of the AR(p) process (i.e. \( x_0, x_1, \ldots, x_{N-1} \)) and suppose this can be generated 'equally well' by the AR model of order \( g \max p \) with lags \( \{j_1, j_2, \ldots, j_g\} \). (The purpose of this technique is to find the best subset AR model of order \( g \max p \).)

Let \( P_g = g \times g \) matrix with \( r^{th} \) element \( \phi _{r-s} \) (\( r, s = 1, 2, \ldots, g \))

and \( R = (\phi _{j_1}, \ldots, \phi _{j_g}) \)

hence we may estimate these by

\[
\hat{R}_g = \left( R_{j_1} - \phi _{j_1} \right) \left( \begin{array}{c} \vdots \\ \phi _{j_g} - \phi _{j_1} \end{array} \right)
\]

and \( t_2 = (\phi _{j_1}, \phi _{j_2}, \ldots, \phi _{j_g}) \)

Define \( t_2 \) to be an estimate of \( t_2 \) (if we are given \( \phi _{j_1} \) (or \( \phi _{j_2} \)) then

\[
\hat{t} = R^{-1} R_{j_1} \quad \text{(called the modified Yule-Walker equations)}
\]

and \( \hat{t}_2 = \phi _{j_1} \left( 1 - R_{j_1} \hat{R}_g^{-1} R_{j_2} \right) \)

To estimate \( \hat{t}_2 \) we need the 'best' AR model of each order \( g \max p \) \((g = 1, 2, \ldots, p)\).

McClave (1975, 1978) gives the following procedure for determining the best AR model for a fixed \( g \):

(i) compute \( \hat{t}(1) \) \((i=1, 2, \ldots, p)\) where \( \hat{t}(i) \) is the increase in the estimated residual variance when lag \( i \) is removed from the AR model of order \( p \max p \)

(ii) order the \( \hat{t}(i) \) such that \( \hat{t}(1) \preceq \hat{t}(2) \preceq \ldots \preceq \hat{t}(p) \)
((iii) let \( q = p - g \)

(iv) remove the lag-1, \ldots, \( q \) from the AR(p) model and compare the increase in residual variance with \( \delta(i_{q+1}) \); if this increase is \( \delta(i_{q+1}) \), the AR model of order \( g \) \max p with smallest residual variance among all \( \binom{p}{g} \) such models, is obtained by removing lags \( i_1, \ldots, i_q \); if this increase \( > \delta(i_{q+1}) \) proceed to the next step

(v) find the minimum increase in residual variance for the set of \( \binom{q+1}{q} \) models obtained by removing each of the subsets of \( q \) lags in \( i_1, i_2, \ldots, i_{q+1} \) compare this minimum increase with \( \delta(i_{q+3}) \); if it is \( < \delta(i_{q+2}) \) stop, otherwise proceed to the next step

(vi) find the minimum increase in residual variance for the set of \( \binom{q+2}{q} \) models obtained by removing each of the subsets of \( q \) lags in \( i_1, i_2, \ldots, i_{q+2} \); if this increase is \( < \delta(i_{q+3}) \) we have found the 'best' subset model of order \( g \) \max p, otherwise continue in this manner

Doing this for each \( g (g=1, \ldots, p) \) we eventually obtain a set of vectors \( \delta_1(1), \delta_1(2), \ldots, \delta_1(p) \) where \( \delta_1(i) \) is an estimate of \( \delta_1 = \{ k : j_1, j_2, \ldots, j_k \} \) for the case when \( g = 1 \).

We now need to estimate the 'best' \( g(-1, 2, \ldots, p) \) and hence use \( \delta_1(g) \) to estimate \( \delta_1 \).

McClave (1975, 1978) suggests the following

(1) compute \( \delta_0; \ldots, \delta_{p-1} \)

This technique may cause one to stop too early, however the result should be close enough (McClave: 95)
where 
\[ \hat{r}_k = \frac{(N-k-s-1)(\hat{\sigma}^2_k - \bar{\chi}_k)}{\hat{\sigma}^2_k} \]

\((k=0, \ldots, p-1)\)

and \( \hat{\sigma}^2 = \text{residual variance corresponding to the set of nonzero lags in } \bar{\chi}_1(k) \)

\(s = \text{no. of functionally independent parameters in the estimated model (usually } k)\)

(ii) for a given choice of \(k\), find \(d_k\) such that

\[ P(\hat{r}_k > d_k) = a \]

where \(\hat{r}_{k+1}\) is the maximum order statistic in a sequence of \(p-k\) independent \(\chi^2\) random variables

(iii) choose the estimated order \(\hat{g}\) such that

\[ \min k : \hat{r}_k < d_k, \quad 0 \leq k < p \]

then \( \bar{\chi}_1 = \bar{\chi}_1(\hat{g}) \)

Thus \( \bar{\chi}_1\) may be estimated.

Some to fit an MA subset model of order \(g_{\text{max}} q\) with nonzero lags \(j_1, j_2, \ldots, j_g\), it is sufficient to find estimates of \(I(k)\) the inverse acr coefficients - which is equivalent to having estimates of the acr of an AR model of order \(g_{\text{max}} q\) with nonzero lags \((j_1, j_2, \ldots, j_g)\). Exactly the same procedure is used as for the AR method except that all acr are replaced by the iacr.
APPENDIX A16: TRANSFORMED SERIES

Often, before or after we apply Box-Jenkins models, a (preliminary) transformation is required. A family of transformations presented by Box and Cox (1964) is given by

\[ X_{\lambda,t} = \begin{cases} \frac{x_t^\lambda - 1}{\lambda} & \lambda \neq 0 \\ \log(x_t + \lambda x) & \lambda = 0 \end{cases} \]

where \( \{x_t\} \) is a positive nonstationary series and \( \lambda \) is transformation parameter. \( \{X_{\lambda,t}\} \) = transformed series.

In the case where some of the \( x_t^\lambda < 0 \)

\[ X_{\lambda,t} = \begin{cases} \frac{(x_t + \lambda)^\lambda - 1}{\lambda} & \lambda > 0 \\ \log(x_t + \lambda^2) & \lambda = 0 \end{cases} \]

This family of transformations holds for \( x_t^\lambda > 2 \forall t \) (see Box and Cox (1964)).

Ansley, Spivey and Wrobieski (1977) have designed an algorithm to find nonlinear LSEs of \( \lambda \) and the other model parameters. (Also see Vera and Guerrero (1981)).

Granger and Newbold (1976) considered the following problem: given a time series \( \{x_t\} \) and a set of forecasts \( x_t(\ell) \) (\( \ell = \) lead time), how do you find forecasts for a transformation of \( \{x_t\} \)? This is related to the next appendix, i.e. A17).

Suppose \( x_t^\lambda = T(x_t) \forall t \) where

\[ T = \text{some well-behaved function, and } \{x_t\} \text{ is a stationary Gaussian series with mean } \mu \text{ and variance } \sigma^2 \text{ (and acf } \rho(k)). \]
Let \( y \) and \( y_{t-k} \) be jointly distributed as a bivariate normal with mean zero, unit variances and correlations \((\kappa)\).

Consider \( x_{t} = T(y_{t}) \) with the expansion

\[
T(Z) = \sum_{j=0}^{\infty} \alpha_{j} H_{j}(Z)
\]

where \( H_{j}(Z) \) is Hermite polynomial such that

\[
H_{n}(x) = e^{x^{2}} \frac{d^{n}}{dx^{n}} e^{-x^{2}/2}
\]

or

\[
H_{n}(x) = (-1)^{n} f^{(n)}(x)/f(x)
\]

where \( f \) is a std. normal pdf.

Explicitly,

\[
H_{n}(x) = \frac{(-1)^{n}}{n!} \left( \frac{\partial^{n}}{\partial x^{n}} \right) e^{-x^{2}/2} x^{n}
\]

and \([k]\) = largest integer < \(k\).

Then

\[
E(y_{t} x_{t}, t-\gamma) = \alpha_{1}(\cdot)
\]

\[
\text{Cov}(y_{t} x_{t}, t-\gamma) = \alpha_{2}(\cdot)\Gamma
\]

\[
\text{Cov}(x_{t} x_{t}, t-\gamma) = \sum_{j=1}^{\kappa} \alpha_{j}^{2} \Gamma_{j}^{(j)}
\]

\[
\text{V}(y_{t}) = \sum_{j=1}^{\kappa} \alpha_{j}^{2} \Gamma_{j}^{(j)}
\]

where the jth term of \( x_{t} \) is \( n_{j}(\cdot) = \sum_{j=1}^{m} \alpha_{j}^{2} J_{j}^{(j)} \Gamma_{j}^{(j)} \Gamma_{j}^{(j)} \Gamma_{j}^{(j)} \).

If \( \Gamma(\cdot) \) for \( t = 0 \)

then \( \alpha(t) \) for \( m = 1 \) (i.e. in the expansion i.t.o. Hermite polynomials).
If at time $n$, we have $\hat{x}_n(h) = \text{forecast of } x_{n+h}$, let

$$\hat{x}_{\lambda,n+h} = T(\hat{x}_{n+h}) = T\left(-\frac{x_{n+h} - \mu}{\sigma}\right)$$

Granger and Newbold (1976) claim that

$$\hat{x}_{\lambda,n,h}(h) = T\left(-\frac{x_n(h) - \mu}{\sigma}\right)$$

is invariably the most practical forecast of $x_{\lambda,n+h}$.
APPENDIX A17 : FORECASTING

Suppose the data are generated by the model $x_t = (B)x_{t-1} + (B)a$, i.e. an ARMA $(p,q)$ model (and $X$ is a stationary process).

$x_{t+1}$ can be represented in three ways.

(a) In terms of a difference equation

$$x_{t+l} = \phi_1 x_{t+l-1} + \cdots + \phi_p x_{t+l-p} - \theta_1 a_{t+l-1} - \cdots - \theta_q a_{t+l-q} + \epsilon_{t+l}$$

(b) In terms of values (past and present) of the white noise $a_t$

$$x_{t+l} = \sum_{j=-\infty}^{0} \sum_{j=m}^{l} a_{t+l-j}$$

(c) In terms of previous $x$ values and noise i.e.

$$x_{t+l} = \sum_{j=1}^{\infty} \sum_{j=m}^{l} x_{t-l-j} a_{t+l-j}$$

[see Box and Jenkins (1976), pg. 94; also see section 6.6 for the relationship between the $\phi$, $\theta$ weights and $\phi_1, \ldots, \phi_p, \theta_1, \ldots, \theta_q$.]

Suppose we are at origin $t$ and wish to forecast $x_{t+1}$, $x_{t+2}$, etc. i.e. $x_t(1)$, $x_t(2)$, etc. and suppose the best forecast of $x_{t+l}$ at time $t$, using (a.17.1), is

$$x_t(l) = \alpha_l a_t + \alpha_{l+1} a_{t-1} + \cdots + \alpha_j a_{t-j} + \cdots$$

The MSE of the forecast is

$$E(\sum_{t+l-j=0}^{\infty} a_t^2) = \sum_{j=0}^{\infty} \alpha_j^2 + \cdots + \alpha_{l-1}^2 a_t^2 + \sum_{j=0}^{\infty} (\sum_{j=0}^{\infty} \alpha_j^2) a_t^2$$

(using (a.17.1)).

This is minimized when $\alpha_{l+j} = \alpha_{l+j}$

$$x_{t+l} = \alpha_{l} a_t + \cdots + \alpha_{l} a_{t-1}$$

$$+ \alpha_{l+1} a_{t+1} + \cdots + \alpha_{l+1} a_{t-1}$$

$$+ \cdots + \alpha_{l+j} a_{t+j} + \cdots$$
\[ a_t(z) + \sum_{t=1}^{\infty} x_t(z) \]

say \( a_t(z) \)

\[ e_t(1) = x_{t+1} - x_t(1) = x_{t+1} \]

- one step ahead forecast error (which is uncorrelated with any other one step ahead forecast error)

\[ \hat{e}_t(i) = \sum_{j=1}^{\infty} E(x_{t+j}/x_t(x) \cdot x_{t-1}(\ldots)

(by using (a17.2))

e.g. if \( x_{t+1} = x_{t+1} \cdot x_{t-1} + x_{t+1} \cdot x_{t-2} + a_{t+1} \)

then

\[ \hat{x}_t(1) = \hat{x}_t(1) + x_{t-1} \]

\[ \hat{x}_t(2) = \hat{x}_t(1) + x_{t-2} \]

\[ \hat{x}_t(3) = \hat{x}_t(2) + x_{t-2} \]

\[ \hat{x}_t(i) = \hat{x}_t(i-1) + x_{t-2} \]

\[ \hat{x}_t(i) = i = 3, 4, 5, \ldots \]

Suppose forecasts at lead times 1, 2, \ldots, L are required. If we are to use an updating procedure, a, \ldots, a_L are required. These can be obtained by solving

\[ \tau(B) \cdot \gamma(B) = \beta(B) \]

i.e. \( (1 - B - \ldots - B^p)(1 - \frac{1}{B^q} - \ldots) = (1 - B - \ldots - B^q) \)
This results in

\[ a_1 = \beta_1 = 0 \]

\[ a_2 = 2 \beta_1 + \beta_2 = \beta_1 \]

\[ a_j = \beta_1 a_{j-1} + \ldots + \beta_p a_{j-p} - 8_j \]

Knowledge of \( \beta_1, \ldots, \beta_p \) implies knowledge of the \( \beta_i \).

Since \( x_{t+1}^{(l)} = x_t^{(l)} + a_t + \ldots \)

and \( x_t^{(l+1)} = x_t^{(l)} + a_t + a_{t-1} + \ldots \)

then \( x_{t+1}^{(l+1)} = x_t^{(l+1)} + a_t + a_{t-1} \)

By (A17.3), \( e_t^{(l)} = x_t^{(l)} - \hat{x}_t^{(l)} \)

so

\[ V(e_t^{(l)}) = (1 - 0_1^2 - 0_2^2 - \ldots - 0_p^2) a_q \]

If the \( a_t \) are independent and normally distributed (with mean zero),

then the approximate 1 - \( \alpha \) probability limits for \( x_t^{(l)} \) are

\[ x_t^{(l)} \pm z_{\alpha} \left( \frac{1}{2} - \frac{1}{2} \ldots - \frac{1}{2} \right)^{1/2} \]

where \( s_n = \text{estimate of } \frac{1}{2} \)

\( z_{\alpha} = \text{deviate exceeded by a proportion } \frac{1}{2} \text{ in } N(0,1) \)

\( \frac{1}{2} \text{ distribution} \)

E.g. suppose \( x_t^{(l)} \) is generated by an ARMA(1,1) model (\( x_t^{(l)} \) is stationary) i.e.

\( (1 - \phi B)x_t = (1 - \theta B)a_t \)

then

\[ x_t^{(l)} = x_t^{(l-1)} \]

\[ x_t^{(l)} = x_t^{(l-1)} + a_t \]

\( i \geq 2 \)
and so

\[ x_{t+1}^{(i)} = x_t^{(i+1)} + (\phi - \Theta) a_{t+1} \]

Also, since \( e_j = (\phi - \Theta) a_j^{(j-1)} \) \( j = 1, 2, \ldots \)

and \( e_j = (\phi - \Theta) a_j^{(j-1)} \) \( j = 1, 2, \ldots \)

\[ V(e_t^{(i)}) = \sigma^2 \left( 1 + (\phi - \Theta)^2 \left( \frac{1 - 2^{j-2}}{1 - \phi^2} \right) \right) \]

**Correlation between forecast errors**

Since \( e_t^{(i)} = a_{t+1}^{(i+1)} + a_1^{(i+1)} a_{t+2}^{(i+1)} + \ldots + a_i^{(i+1)} a_{t+i}^{(i+1)} \)

and \( e_t^{(i)} = a_{t+1}^{(i)} + a_1^{(i)} a_{t+2}^{(i)} + \ldots + a_i^{(i)} a_{t+i}^{(i)} \) \( j < i \)

then

\[ \text{Cov}(e_t^{(i)}, e_t^{(i-j)}) = \sigma^2 \left( \frac{1}{i} \right) \left( 1 - j \right) \] \( (i = 1) \)

= acvf of the forecast errors

Similarly, the acvf are

\[ \text{Cov}(e_t^{(i)}, e_t^{(i-j)}) = \begin{cases} \frac{1}{i} - j & 0 \leq j < i \\ i & j = i \\ 0 & j > i \end{cases} \]

In a similar manner it can be shown that

\[ \text{Cov}(e_t^{(i)}, e_t^{(i+j)}) = \begin{cases} \frac{1}{i} - j & 0 \leq j < i \\ i & j = i \\ 0 & j > i \end{cases} \] for more detail see Box and Jenkins, 1976, chapter 5]
Due to the large amount of computation needed for the effective analysis of a time-series, it is generally necessary to develop a suite of computer programs. Such a suite was developed during the preparation of this dissertation, and a description of the programs is given in this appendix.

All programs were written in Fortran IV in conversational mode, and implemented on the IBM SYSTEM/370.

The programs used were:

1. PGRAM
2. HIDPEP
3. MINVA
4. AUTOAR
5. BJID
6. BJES
7. BJFO
8. AUTO
9. SPEC
10. TRANS
11. BUYBAL
12. PITEST
13. QBPLOT

In the foreseeable future it is intended that all these programs will be condensed into one package and will allow the user either no control (i.e. fully-automatic) or selective control.

1. PGRAM (Periodogram computation)

This program is adapted from Bloomfield (1976, pg. 114) and computes the discrete Fourier transform of a time series, and hence the periodogram. The transform is computed by using the Tukey-Cooley fast Fourier algorithm (Cooley and Tukey (1965)).
This basically just involves extending the time-series by zeroes to the next power of 2 above \( N \) (the length of the series) and calculating the discrete Fourier transform \( J(w) \) for \( w_j = 2\pi j/N' \) (\( N' \) = next power of 2 above \( N \)).

**Input (besides the time-series)**

(a) length of time series (i.e. \( N \))

(b) ordinates of the section of data of interest

(c) \( K = 0 \) or \( 1 \) - the degree of the LS polynomial to be removed from section of interest

(d) the degree of tapering required (see section 5.4.2)

Only the section of data given by (b) is used. The next power of 2 (i.e. \( N' \)) is computed automatically.

**Output**

(a) the degree of the polynomial removed

(b) the degree of tapering

(c) a plot of \( \log_{10} \bar{R}(w)^2 \)

\[
\bar{R}(w)^2 = \bar{A}(w)^2 + \bar{B}(w)^2
\]

\[
\bar{A}(w) = \frac{1}{N'} \sum_{i=1}^{N'} (x_i - \bar{x}) \cos(wt)
\]

\[
\bar{B}(w) = \frac{1}{N'} \sum_{i=1}^{N'} (x_i - \bar{x}) \sin(wt)
\]

\( \bar{R}(w)^2 \) differs from \( I(w) \), the periodogram by a factor of \( 8^{-N'N'} \). It is more useful in harmonic analysis since it represents the LS estimate of the squared amplitude of a sinusoid of frequency \( w \).

\( \bar{R}(w)^2 \) is plotted against \( j \) where \( w_j = 2\pi j/N' \) and

\[
j = 1, \ldots, \frac{N'}{2} \quad (i.e. \ 0 < w_j < \pi)\]
The logarithm is used due to the variation in the order of magnitude of the periodogram between different frequencies. If only the periodogram is plotted (i.e. not the $\log_{10}$) so that the largest value is on the graph, then details at higher frequencies may be obscured (i.e. the $\log_{10}$ plot just reduces the range).

(2) **HIDPER** (Search for hidden periodicities)

This program is adapted from Bloomfield (1976, pg. 33) and fits the model

$$x_t = \sum_{k=1}^{m} a_k \cos(w_k t) + b_k \sin(w_k t) + \epsilon_t$$

to the data.

**Input** (besides the time-series)

- (a) length of the time-series
- (b) ordinates of the section of the data of interest
- (c) $m$ (the no. of frequencies)
- (d) initial estimates of $w_1, w_2, \ldots, w_m$ (gauged from PGRAM)
- (e) initial estimates of $a_1, \ldots, a_m$ and $b_1, \ldots, b_m$ (usually zero)
- (f) $L = \begin{cases} 0 & \text{if exact LS method is required} \\ 1 & \text{if approximate method is required} \end{cases}$

(see section 3.2)

The program then computes either exact LS estimates or approximate LS estimates of $w, a, b$ using subprogram LOCALM from Brent(1973) [this finds a local minimum of a multi-parameter function $f$ in interval $(u,v)$.]
Output

(a) whether exact/approximate LS method is used
(b) initial values of frequencies and sine and cosine coefficients
(c) optimum values of frequencies and sine cosine coefficients
(d) fitted constant (i.e. \( \hat{U} \))
(e) the (exact or approximate) residual sum of squares

(3) MINVAR (Inducing stationarity)

This program is based on the procedure used by Hill and Woodworth (1980) for determining \( d \) and \( D \) - the degrees of nonseasonal and seasonal differencing resu.
i.e. calculate

\[
\min_{d,D,S} \frac{1}{n} \sum_{t=1}^{n} \left| \frac{X_t - f(d,D,S)}{S^2} \right|^2,
\]

where \( S = T^{\frac{1-D}{D}} \),

\( S = \) seasonal base

Input (besides the time-series)

(a) maximum values of \( d, D, S \)
(b) length of the time-series
(c) ordinates of the section of interest.

The program now tries all combinations of values (for \( d, D \) and \( S \)).
The variances of the differenced series are sorted into ascending order.

Output

(a) the variances of the differenced series (in ascending order) with associated \( d, D, S \), as well as the coefficient of variation associated with each series (this just provides another criterion for determining \( (d, D, S) \)).
(4) **AUTOAR** (Automatic AR model fitting)

This program fits successive auto-regressive mode s up to some specified maximum order i.e. AR(1), AR(2), ..., AR(p).

**Input** (besides the time-series)

(a) length of series
(b) ordinates of section of interest
(c) degree of seasonal differencing and seasonal base
(d) degree of nonseasonal differencing
(e) maximum value of p (i.e. the highest order AR model required).

If differencing is required, the program first computes this. Then the acrf (and acvf) is calculated up to a lag greater than the p given in (e). The Yule-Walker equations are then solved i.e. solve \( \hat{\beta} = R^{-1} r \).

where

\[
\hat{\beta} = (\hat{\beta}_1, \ldots, \hat{\beta}_p)^T
\]

\[
r = (r_1, \ldots, r_p)^T
\]

\[
R = \begin{pmatrix}
1 & r_1 & r_2 & \ldots & r_p \\
r_1 & 1 & r_1 & \ldots & r_{p-1} \\
r_2 & r_1 & 1 & \ldots & r_{p-2} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
r_p & r_{p-1} & r_{p-2} & \ldots & 1
\end{pmatrix}
\]

for each \( k = 1, 2, \ldots, p \)

Calculate

\[
\hat{\sigma}^2_{a,k} = \hat{\beta}_0 - \sum_{i=1}^{p} \hat{\beta}_i c_i^2
\]

for each \( k \)

**Output**

(a) the parameter estimates for each AR model
(b) the associated white noise variance estimate \( \hat{\sigma}^2_{a,k} \)
(c) AIC and CAT (as defined in section 7.4.2.) for each AR model - this enables the user to decide which AR model gives the best fit.

(5) BJID (Box-Jenkins identification)

This program is a modification of that described in Box and Jenkins (1976), pg. 496 and helps in the initial stages of model identification. It consists of two sections - an editing phase and an identification phase. The editing phase allows one to transform the data, replace certain values, plot the data etc.

The identification phase provides plots of the acrf, pacrf, iacrft and ipacrf.

Input (besides the time-series)

(a) length of the series
(b) ordinates of section of interest
(c) any changes to be made in the editing phase
(d) degree of seasonal differencing and seasonal base
(e) degree of nonseasonal differencing
(f) maximum lag of the acrf
(g) maximum lag of the pacrf
(h) 4 values (between 10 and 50) which denote the maximum AR model to be fitted and hence the iacrft and ipacrf (see appendix A12).

Firstly, any desired changes to be made by the editing phase are made. If differencing is required, this is carried out. Using the value given in (f), the Yule-Walker equations are solved (as in program (3), AUTOAR).
Using the technique described in appendix A10, and the value in (g), the pacrf is plotted. A technique, described by Chatfield (1979), for estimating the iacrfs, is given in appendix A12. This technique is used for each of the 4 values given in (h). To find the ipacrfs, the 'inverse' Yule-Walker equations must be solved i.e.

\[
\begin{bmatrix}
1 & \alpha(1) & \ldots & \alpha(k-1) \\
\alpha(1) & 1 & \ldots & \alpha(k-2) \\
\vdots & \vdots & \ddots & \vdots \\
\alpha(k-1) & \alpha(k-2) & \ldots & 1
\end{bmatrix}
\begin{bmatrix}
\theta_1 \\
\theta_2 \\
\vdots \\
\theta_k
\end{bmatrix}
= \begin{bmatrix}
\phi(1) \\
\phi(2) \\
\vdots \\
\phi(k)
\end{bmatrix}
\]

\(\theta_k\) is one of the 4 values given in (h).

Replace \(\phi(i)\) by \(r_i(\lambda)\) and solve for \(\theta_k\) (\(j = 1, \ldots, k\))

\(\theta_k\) is called the sample ipacrfs.

The user is left to decide which of the 4 iacrfs/ipacrfs representations is appropriate.

The user may now also wish to 'fit' some BJ models and the only input required are the values for \(p\) and \(q\) in the desired ARMA \((p, q)\) process. Model parameters are estimated by

1. if \(p > 0\), solving

\[
A \zeta = c
\]

where

\[
A_{ij} = c_{j-i-1} \\
c = (c_0, \ldots, c_p)
\]

and

2. if \(q > 0\), use the procedure described in appendix A9.
(iii) the overall constant in the model is estimated by

\[
\hat{c} = \begin{cases} 
\frac{x(1 - \sum_{i=1}^{p} \frac{b_i}{\sigma^2})}{\sigma^2} & p > 0 \\
\frac{x}{\sigma^2} & p = 0 
\end{cases}
\]

and the white noise variance by

\[
\hat{\sigma}^2 = \begin{cases} 
\frac{\sum_{i=1}^{q} e_i^2}{\sigma^2} & q > 0 \\
\frac{c_0 - \sum_{i=1}^{p} \frac{\sigma^2}{\sigma^2}}{\sigma^2} & q = 0
\end{cases}
\]

\((\hat{\sigma}^2 \text{ from appendix A9 and } \bar{x} \text{ the mean of the series})\)

Output

(a) mean of (differenced) series
(b) variance of (differenced) series
(c) degrees of differencing
(d) acrft
(e) pocrft
(f) vaacrft and ipacrft for each of the 4 values desired
(g) estimates of model parameters (if so required), overall
constant in the model and white noise variance.

This program is 'recursive' i.e. it allows several successive
runs of the program for different editing phases, degrees of
differencing, models etc.

The initial estimates (of model parameters) required in
the next program are given in (g).

[Note that the Box-Jenkins progs 1 and 2 (Box and Jenkins (1976)
pag. 496+) do not calculate vaacrft or ipacrft.]
BJES (Box-Jenkins model estimation).

This program is an adaptation of the program (3) described in Box and Jenkins (1976, pg. 300) and uses the initial estimates of the nonseasonal parameters from program (5) (BJID) (and if seasonal parameters are required then a technique described by Box and Jenkins (1976), chapter 9, provides initial estimates of the seasonal parameters) this program calculates LSE's for \( \mu, \phi, \theta, \psi, \phi', \theta', \) and \( \phi'' \) (the seasonal parameter vectors) in the model

\[
\psi(B)(x_t - \mu) = \phi(B)\alpha_t ,
\]

or \( \phi(B)\psi(B')(x_t - \mu) = \phi(B)\phi'(B')\alpha_t , \)

where \( x_t \) is a stationary series.

**Input** (besides the time series)

(a) length of series, \( N \)

(b) ordinates of section of interest

(c) degrees of differencing

(d) initial estimates of all parameters (i.e. \( p,q,p^*,q^*,S \) and hence all parameter values)

The program calculates backforecasts of the \( x_t \)'s (see section 7.3.1) and hence

\[
S(\mu, \phi, \theta, \psi, \phi', \theta', \phi'') = \sum_{t=k}^{N} \hat{\alpha}_t^2 .
\]

The values which minimize \( S \) are obtained by the constrained optimization technique of Marquardt (1963) (which is described fully in Box and Jenkins, 1976, pg. 504). These values are the LSE's.

An estimate of the residual variance is then obtained using these LSE's, and the covariance matrix of the (optimum)
estimates is given by
\[ \hat{i} = (X'X)^{-1} \sigma^2 \]

(Where \( X \) is the regression matrix in the linearized model). The
standard errors of the estimates are given by
\[ \hat{\sigma}_i = \sqrt{\hat{\sigma}^{11} (\hat{\sigma} = \hat{\sigma}^{11})} \]

An estimate of the overall constant in the model is given by
\[ \hat{\gamma} = \gamma L \]

Where
\[ L = (1 - \frac{1}{e_i \hat{\phi}_1}) \]

(or if the model is seasonal
\[ L = (1 - \frac{1}{e_i \hat{\phi}_1})(1 - \frac{1}{e_j \hat{\phi}_j}) \]

The residuals \( \hat{a}_i \) corresponding to the LSE's are calculated and
hence the acrf of the residuals (for some set lag). The mean and
variance of the residuals are also given. The acrf of the
residuals is plotted as well as 1% significance levels (using the
 technique of Hipel et al (1977)).

Output
(a) Initial and final estimates of the parameters
(b) White noise variance estimate
(c) Standard errors and covariance matrix of the estimates
(d) \( \hat{\gamma} \), the overall constant
(e) Residual acrf (a plot) and 1% significance levels

(7) RJFO (Rox-Jenkins forecasting)

Using the LSE's from program 6, (RJES), this program forecasts

future values of the series \( \{X_t\} \) using the techniques described
in appendix A17. This program is described in Box and Jenkins (1976), pg. 505.

(8) AUTO (Subset autoregression technique)
Using the procedure of McClave (1975, 1978, 1978a) - see appendix A15 - the user specifies a maximum order AR model and the program then finds the best-fitting AR model (using AIC and CAT criteria). Having found the 'optimum' AR order, the program now finds the best subset autoregression for each different subset size (again using the above-mentioned criteria). For each 'full' AR model, parameters are given, and the parameters are also given for each best subset in the optimum 'full' model. For more details, see appendix A15. (Also see Gabr and Subba Rao (1981)).

(9) SPEC (A spectrum estimate)
This program calculates the sample acrf (acvf) and based on this, computes an estimate of the nsdf (see equation (4.9), section 4.2 - divide both sides by \( \frac{1}{1} \)).

Input (besides the time series)
(a) length of time series, N
(b) ordinates of section of interest
(c) the number of spectral windows to be used - 10 are offered - and the specific windows to be used.

The program automatically computes the sample acrf (up to lag 0.75 \( \times \) N). The ten windows offered are:
Truncated periodogram, Bartlett A, Bartlett B, Daniell, Tukey-Hamming, Tukey-Hamming, Parzen A, Parzen B, Bartlett-Priestley and Tukey-Parzen. The truncation points \( M \) (for each window)
are 5%, 10%, 20%, 40%, 50%, and 75% of \( N \) (i.e. for each window, six spectrum estimates are given). The spectra are evaluated at \( w_j \) where \( 0 \leq w_j \leq \pi \) (and \( j = 0, 1, \ldots, \left[ \frac{N}{2} \right] \)) and \( w_j = \frac{2\pi j}{N} \).

Output (for each desired window)

(a) 6 spectral estimates (each at the associated truncation point)

(10) **TRANS** (Box-Cox transformation)

In appendix A1d, a family of transformations is presented.

These transformations take the form

\[
X_{\lambda, t} = \begin{cases} 
\frac{x^\lambda - 1}{\ln x} & \lambda = 0 \\
x_t & \lambda = 1
\end{cases}
\]

(assuming all the \( x^\lambda \geq 0 \)).

What value should \( \lambda \) take?

Veras and Guerrero (1981) have proposed a method for finding \( \lambda \) in the following class of transformation (a special case of the above).

\[
X_{\lambda, t} = \begin{cases} 
x_t^{1-\lambda} & \lambda = 1 \\
x_t & \lambda = 1
\end{cases}
\]

Divide the data into subseries of some set length. For each subset calculate the mean \( Z \), standard deviation \( S \) and the ratio \( S^*/Z^* \) (for each \( \lambda \) [a,b] say) where \( S^* = 1000 \times S \) and \( Z^* = (1000 \times Z)^{\lambda} \).

Supposing there are \( \lambda \) subseries of length \( L \), the program calculates the mean, \( \lambda \), of the \( S^*/Z^* \) (for each \( \lambda \)), as well as the standard deviation, \( S_{\lambda} \) of the \( S^*/Z^* \). The coefficient of variation is defined by

\[
CV = \frac{S_{\lambda}}{Z_{\lambda}}
\]
The value of \( \lambda \) giving a minimum value to CV is defined to be the transformation parameter. Successive runs with different lengths of subseries are possible.

**Input** (besides the time-series)

(a) length of series, \( N \)
(b) ordinates of section of interest
(c) length of the subseries, \( L \)

The program divides the data into an integer number of subseries of length \( L \) and calculates \( Z^* \) and \( S^* \) for each subseries.

(d) lower bound, upper bound and increment of \( \lambda \)

**Output**

(a) the coefficient of variation and associated \( \lambda \) (and obviously the length of the subseries)

(11) **BUYBAL** (Buys-Ballot test for period)

A procedure for testing for an assumed period is described in appendix A6. This program performs that procedure.

**Input** (besides the time-series)

(a) length of the time-series
(b) ordinates of section of interest
(c) minimum and maximum values of the 'assumed' periodicity.

**Output**

(a) a plot of the values \( r \) (see appendix A6) for each 
    (integer) value between the minimum and maximum given in
    (c) above
(12) PITEST

This program tests for the existence of the discrete spectrum using Priestley's $P(l)$ test as described on pg.216 (or see Priestley (1962a,b)) using the Bartlett (a) window (see pg. 77).

Input (besides the time-series)
(a) length of the series, $N$
(b) ordinates of section of interest
(c) lower truncation point
(d) upper truncation point
(e) lag at which the peak occurs

Output (after the entry of (a) - (d))
(a) a plot of the acrf
(b) a listing of the acr's
(c) a plot of $P^*(\lambda)$
(d) a listing of $P^*(\lambda)$ ordinates

Upon entry of (e) (in the input), the peak is tested for significance.

(13) QBPLOT

This program plots the quantile-box plot of the data using the technique described in section 9.2 and Parzen (1979).

Note: In each program, if the ordinates of the section of interest are not 1 and $N$ (representing $x_1$ and $x_N$), then the program considers the series between these ordinates to be the (new) series and the length of this section the new $N_j$.

Listings of two of the programs (SPEC (9) and PITEST (12)) follow and serve as exemplars of the suite.
PROGRAM SPEC

PROGRAM TO CALCULATE ACRE AND PERFORM A SPECTRAL ANALYSIS OF THE DATA

APPENDIX A19: RESULTS RELEVANT TO THE CHAPTER 9 AIRLINE DATA

This appendix contains several subsidiary results relevant to chapter 9. These results consist of the following tables and figures.

Tables

A19.1 Listing of the original data ('rad across)
A19.2 Listing of log_{10} of the data given in table A19.1
A19.3 The first 156 observations in the original data set are divided into subsets of size 13, and for each subset the mean, variance and acrf are calculated (this enables one to roughly ascertain whether the data is stationary or nonstationary).
A19.4 The same as table A19.3, except a subset length of 26 is used
A19.5 The same as table A19.3, except a subset length of 52 is used.
A19.6-A19.8 A similar situation to tables A19.3-A19.5 except that the log_{10} of the data is used

Figures

A19.1 The acrf of the first 150 observations in the original series.
A19.2 A spectral estimate (using the Parzen window) of the first 150 observations, in the original series, with a truncation point of M = 75 = 50% of N (N=150).
A19.3 Same as A19.2 but with a truncation point of 75.
A19.4 Output of UYBAL (see appendix A18) applied to the first 150 data points in the original series.
APPENDIX A19 : RESULTS RELEVANT TO THE CHAPTER 9 AIRLINE DATA

This appendix contains several subsidiary results relevant to chapter 9. These results consist of the following tables and figures.

Tables
A19.1 Listing of the original data (read across)
A19.2 Listing of $\log_{10}$ of the data given in table A19.1
A19.3 The first 156 observations in the original data set are divided into subsets of size 13, and for each subset the mean, variance and scrf are calculated (this enables one to roughly ascertain whether the data is stationary or nonstationary).
A19.4 The same as table A19.3, except a subset length of 26 is used
A19.5 The same as table A19.3, except a subset length of 52 is used
A19.6-A19.8 A similar situation to tables A19.3-A19.5 except that the $\log_{10}$ of the data is used

Figures
A19.1 The scrf of the first 150 observations in the original series.
A19.2 A spectral estimate (using the Parzen (b) window) of the first 150 observations, in the original series, with a truncation point of $M = 75 = 50\%$ of $N$ ($N=150$).
A19.3 Same as A19.2 but with a truncation point of $75\%$
A19.4 Output of HUYRAL (see appendix A18) applied to the first 150 data points in the original series.
A19.5-A19.10 The (Parzen (b)) spectral estimates of the first 150 data points in the log_{10} transformed series for truncation points 7, 15, 30, 60, 75 and 112 (i.e. 5%, 10%, 20%, 40%, 50% and 75% of N=150).

A19.11 Autocorrelogram (up to lag 148) of the transformed data.
A 19.3

HANNAN, E. J. (1960)

TIME SERIES ANALYSIS
The effects of reservoir operation on hydrological processes have been studied extensively. Hipel et al. (1977) modeled the statistical behavior of reservoir systems, while Hosking (1980) analyzed the asymptotic distribution of the sample inverse autocorrelation functions. Isserlis (1918) contributed to the understanding of the product moment coefficient of a normal distribution in any number of variables.

General considerations in the analysis of spectra have been developed by Jenkins (1961) and Jenkins and Watts (1968). The periodogram in spectral analysis, as well as other techniques, has been discussed by Jones (1962, 1965) and others.

Kannan (1979) provided an introduction to stochastic processes, while Lamperti (1977) focused on stochastic processes in general. Lomnicki (1961) tested for departure from normality in the case of linear stochastic processes.
