Pre-eclampsia: the outcome of term pregnancies at Rahima Moosa Mother and Child Hospital

Dr Kumesha Naidoo

Promoter: Professor EJ Buchmann

A research report submitted to the Faculty of Health Sciences, University of the Witwatersrand, in fulfilment of the requirements for the degree of Master of Medicine in Obstetrics and Gynaecology

MMed(O&G)

Johannesburg, April 2015
DECLARATION

I, Kumesha Naidoo, declare that this research report is my own work.

It is being submitted for the degree of Master of Medicine in Obstetrics and Gynaecology at the University of the Witwatersrand, Johannesburg.

It has not been submitted before for any degree or examination at this or any other university.

........Kumesha Naidoo............................................

....20........day of .......April........ 2015
DEDICATION

I dedicate this research report to my wonderful parents Dharma and Devi Naidoo whose unconditional love, support and encouragement carried me over the hurdles of this obstacle course.

ACKNOWLEDGMENTS

I thank the following persons for making this research report possible:

- Professor EJ Buchmann for his assistance, supervision and patience with the preparation and execution of this study.
- To the women of the maternity unit at Rahima Moosa Mother & Child Hospital for agreeing to be a part of this study.
- My husband Yugan Naidoo, for the support, and sacrifices of our time together to allow me to complete this research report.

ABSTRACT

Background
Pre-eclampsia and its complications remain a significant cause of maternal and perinatal morbidity and mortality on a global level. There are few data regarding the maternal and fetal outcome of pre-eclampsia at term. Studies suggest that poor maternal outcome is more prevalent as one approaches term, while there are conflicting findings regarding the outcomes of the babies born to term pre-eclamptic patients.

Objective
To determine the prevalence of pre-eclampsia in term pregnancies at Rahima Moosa Mother and Child Hospital (RMMCH), a hospital that provides district and higher level referral services, and to assess the severity of maternal disease in pre-eclampsia at term, as well as fetal outcomes.

Methods
This was a prospective cross-sectional, descriptive study on women giving birth at term with pre-eclampsia. All women were followed up until delivery. The indication for and mode of delivery, maternal progress and complications, as well as fetal outcome, were recorded.

Results
Seventy-eight patients were entered into the study, giving a hospital prevalence rate of pre-eclampsia at term of 1.2%. The major maternal complications were those of severe hypertension (75.6%), eclampsia (9%), HELLP syndrome (3.8%), and pulmonary oedema (7.7%). There was one maternal death. Fifty-one patients (65%) delivered by caesarean section. Major fetal complications encountered were respiratory distress (7.5%) and birth asphyxia (3.7%). There was one neonatal death from meconium aspiration.
Conclusion

This study revealed a significant number of patients having major maternal as well as fetal complications of pre-eclampsia at term. Larger epidemiological studies are needed to predict maternal and fetal outcomes in term pre-eclamptic patients.

1.0 INTRODUCTION

“She gave life. She is a wife. She is a mother and she is a friend. She is a sister, a survivor to the end.” (Ashanti Holliday)(1). All this she is and so much more, what do we do to protect her? Do we dare to care?

It is estimated that 342 900 women die worldwide from pregnancy-related causes (2). Pre-eclampsia and its complications remain a significant cause of maternal and perinatal morbidity and mortality. Globally, pre-eclampsia complicates 2-8% of pregnancies, and 10-15% of direct maternal deaths are pre-eclampsia-related(3). In South Africa, according to the Saving Mothers report of 2008-2010, hypertensive disorders are the second commonest direct cause of maternal deaths (14%) (4). It has been reported that pre-eclampsia and gestational hypertension make up a significant 70% of hypertensive disorders of pregnancy (5).

Pre-eclampsia is a multi-system disease. Although the exact cause is unknown, evidence shows that it arises from the incomplete invasion of the trophoblast, which subsequently results in vasospasm, endothelial dysfunction and ischaemia (6). The disease predominantly affects the circulatory system, the renal system, the central nervous system, coagulation and liver (7).

Management entails admission to hospital and stabilisation of blood pressure with antihypertensive agents if necessary. The patient is assessed clinically, blood and urine are analysed, and an ultrasound and non-stress test are done to assess the viability and well-being of the fetus (7). These investigations give an indication of the severity of disease and guide the further management. The only cure for pre-eclampsia is delivery.

Maternal complications include pulmonary oedema, renal failure, liver failure or rupture, disseminated intravascular coagulopathy, HELLP syndrome, placental abruption,
cerebrovascular accidents, eclampsia and death (7). Fetal growth impairment, placental abortion and perinatal mortality are a consequence of ischaemia due to decreased uteroplacental blood flow.

It has been proposed that pre-eclamptic patients who present at term may have normal to increased utero-placental flow, sparing the fetus from the complications of placental insufficiency that often characterises pre-eclampsia of earlier onset (8). This hypothesis creates the need to explore the outcome of this population of pre-eclamptic patients at term.

The literature is abundant with studies looking at pre-eclampsia and comparing immediate and delayed delivery of such patients. However, the dilemma of immediate delivery versus delaying for maturity of the baby does not exist in the pre-eclamptic patient at ≥37 weeks’ gestation because there is consensus that delivery should be expedited in such women(7).

The aim of this study was to determine the prevalence of pre-eclampsia at term at Rahima Moosa Mother and Child Hospital (RMMCH), a tertiary level hospital that serves the areas around Coronationville in Johannesburg. In view of the above-mentioned hypothesis that pre-eclamptic patients at term have a near normal utero-placental flow compared with those who have early-onset pre-eclampsia, the researcher felt compelled to assess the maternal and fetal outcome in this specific population of pre-eclamptic women.
2.0 LITERATURE REVIEW

Although the literature is overwhelmed with data on pre-eclampsia, it becomes apparent that little work has been undertaken to show the outcome of the pre-eclamptic pregnancy at term. Over the past 20-odd years a large amount of work has been carried out in Africa, Asia, Latin America and the Caribbean, in which this “ongoing holocaust” is described to be killing 10-15% of mothers(3). According to the South African Saving Mothers report of 2008-2010, there was a small reduction in deaths due to complications of hypertension, compared to the previous triennium (4). However, no mention was made of the gestation of pregnancy at which these outcomes were documented.

2.1 Epidemiology

Pre-eclampsia complicates 2-8% of pregnancies worldwide (3). The prevalence varies according to geographic regions of the world, ranging from 2.5% in Saudi Arabia to 4.3% in Turkey, to 5-8% in the USA (6,9,10). This variation may be attributed to racial differences, socioeconomic status and other demographic parameters such as age and parity (10). Pre-eclampsia is described as a disease predominantly affecting nulliparous women, and women at the extremes of their reproductive ages (<20 and >40 years) (9). The exact prevalence of pre-eclampsia in South Africa is unknown, although a 5-year prospective study in Cape Town reported a prevalence of 7.1% (11).

A 10 year retrospective study in Saudi Arabia showed that 42% of pre-eclamptic patients were primigravid (9). Pregnancy, even if it is terminated early, offers some form of immunity to pre-eclampsia in the next pregnancy (12). However, it has been shown that the protective effect of multiparity is lost with a change of partner and also raises the concept of primipaternity rather than primigravidity (11).
Extremes of maternal age, multiple pregnancy, previous pre-eclampsia, chronic hypertension, pre-gestational diabetes, vascular and connective tissue disorder, nephropathy and antiphospholipid syndrome are conditions that predispose a pregnant woman to develop pre-eclampsia. In obesity, although the pathophysiology is unknown, the increased risk for developing pre-eclampsia is postulated to be due to the oxidative stress, inflammation and altered vascular function that have been reported in obese women (13).

African-American race or black race has been shown to be a predisposing factor (6,14). The older literature reports cases of pre-eclampsia in close relatives, however some authors have argued that this was owing to the commonality of the condition and could just as well be coincidental (12). Decades later, the genetic factor still remains and has repeatedly been shown to be a predisposing component to pre-eclampsia (6).

2.2 Definitions and criteria for the severity of pre-eclampsia

The importance of classifying the severity of pre-eclampsia arises when one is faced with an ill patient who is still remote from term gestation. The definitions used in this research report are provided in the list of definitions at the beginning of the report. In the clinical situation, a decision on classification of a patient’s hypertensive disorder has to be made taking into consideration the patient’s clinical condition and risks of morbidity and mortality, as well as delivering a pre-term baby, which has its own consequences. Various classifications exist in which there are criteria to define severe pre-eclampsia. The alternative to those criteria defined as severe are accepted as mild or moderate as they are not specifically defined. Table 1 shows the most recent criteria as accepted by the ACOG (15).

### 2.3 Pathophysiology

Pre-eclampsia is described as a syndrome unique to pregnancy that can affect every organ system. Although the precise aetiology remains elusive, pre-eclampsia has been a topic of research for a very long time, and a number of theories for its pathogenesis have been proposed. Current research has led to the understanding that it is a two-stage disorder. The incomplete or abnormal trophoblastic invasion sets the scene for stage one, the placental disease. In normal placentation, uterine spiral arterioles undergo extensive remodelling by trophoblastic invasion, leading to formation of wide-bore vessels carrying maternal blood to the placenta. In pre-eclampsia, there is incomplete trophoblastic invasion, and therefore the normal pregnancy remodelling of maternal vessels does not happen. This results in the deeper
myometrial arterioles maintaining their pre-pregnancy anatomical structure, thus remaining narrow conduits of blood flow. Their mean external diameter is half that of vessels in normal placentas (16). The effect of these abnormally narrowed spiral arterioles is placental hypoperfusion and hypoxia. Stage two is the maternal clinical syndrome. The placental disease leads to a release of trophoblastic debris, apoptotic cells and anti-angiogenic factors, which induce a maternal systemic inflammatory response and widespread endothelial vascular damage, producing the pre-eclampsia syndrome of high blood pressure, proteinuria and organ dysfunction (16).

2.3.1 Vasospasm and haemoconcentration

Intense vasospasm with endothelial damage and dysfunction in the maternal circulation is caused by the interaction of various vasoactive agents such as prostacyclin (vasodilator), thromboxane A2 (potent vasoconstrictor), nitric oxide (potent vasodilator), and endothelins (potent vasoconstrictors) (6). In pre-eclampsia, compared with normal pregnancy, prostacyclin production decreases, while thromboxane A2 production by platelets is increased, with subsequent increased vascular resistance and hypertension (16). The simultaneous endothelial cell damage results in: 1) decreased production of nitric oxide and release of substances that promote coagulation and increase sensitivity to vasopressors; and 2) a capillary leak of blood constituents, which are deposited subendothelially. This results in haemoconcentration, decreased colloid osmotic pressure, and contraction of the intravascular space. As the endothelium undergoes repair after delivery, the vasoconstriction resolves, and there is a concomitant decrease in the haematocrit levels as the blood volume increases (6).
2.3.2 Haematological changes

A commonly identified abnormality in pre-eclampsia is thrombocytopenia. The intensity may vary according to the severity of the pre-eclampsia. The lower platelet count is associated with higher maternal and fetal morbidity and mortality (17). The thrombocytopenia usually worsens with ongoing pregnancy. After delivery, the decline in platelet count may continue for 48-72 hours. The platelet count then increases gradually and within three to five days should reach normal levels. Haemolysis may also occur simultaneously with the thrombocytopenia. This is reflected by a disproportionate rise in lactate dehydrogenase in the serum (6), and the presence of schizocytosis, spherocytosis and reticulocytosis on a peripheral blood smear. The most sensitive objective marker of haemolysis is a reduced serum haptoglobin level (18,19).

2.3.3 Hepatic changes

Patients with severe pre-eclampsia may have significantly altered hepatic function (6). Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels may be elevated and inversely follow platelet counts. They also usually normalize within three days after delivery. Hyperbilirubinaemia may occur especially when haemolysis is present. Autopsy studies have found that the characteristic lesion commonly found is hepatic infarction and periportal haemorrhage in the liver lobule periphery (16,20). Hepatic haemorrhage may extend to form a subcapsular haematoma that presents clinically as right upper abdominal pain. Hepatic rupture is rare but life-threatening, requiring emergency surgical intervention (6,18).

HELLP syndrome, a variant of severe pre-eclampsia, is associated with substantial mortality and morbidity. It diagnosis is based on laboratory abnormalities. The syndrome has been
reported to occur in 20% of women with severe pre-eclampsia (18). Maternal mortality ranges from 0-4% (18). Other complications associated with HELLP syndrome include acute renal failure in 8% of women, pulmonary oedema in 6%, and subcapsular liver haematoma in 1% (18). Due to the unfavourable cervix and early gestation found in most patients with HELLP syndrome, caesarean delivery is commonly performed. Wound haematoma and subsequent wound sepsis becomes a further complication in this group of patients, due to the low platelet count (18).

2.3.4 Renal changes

In normal pregnancy, there is an increase in renal blood flow with increased glomerular filtration and decreased serum creatinine level. However, due to the vasospasm in pre-eclampsia this physiological change does not occur. Instead, there is decreased glomerular filtration which, together with the haemoconcentration, leads to oliguria and a rise in serum creatinine level. In the glomeruli, there is podocyte dysfunction and endothelial swelling, also termed glomerular capillary endotheliosis, which causes an increase in the permeability of the membrane with subsequent protein leakage into the urine (6).

Acute renal failure is a rare complication of pre-eclampsia and usually resolves spontaneously after delivery (21), although dialysis may occasionally be required. More frequently, acute tubular necrosis is precipitated by haemorrhagic shock which accompanies the other complications mentioned above, mainly placental abruption (21). Rarely, irreversible renal cortical necrosis develops. A five-year prospective study in the United Kingdom showed that 0.55% of women with pre-eclampsia required dialysis based on worsening creatinine levels (22). A prospective case series in Tygerberg Hospital, Cape
Town, reported that 6 out of 340 pre-eclamptic patients (1.7%) had severe renal impairment, of whom one required dialysis (11).

### 2.3.5 Neurological changes

Changes to the cerebral circulation are the primary effectors of the neurological symptoms seen in pre-eclamptic patients. Normally, by the mechanism of autoregulation, cerebral blood flow is maintained at a constant rate despite changes in cerebral perfusion pressures. Blood pressures above and below the autoregulatory limits result in this mechanism being lost. In the case of an acute hypertensive episode at pressures above the autoregulatory limit, the excessive intravascular pressure overcomes the constriction of the vascular smooth muscle with subsequent forced dilatation of the cerebral vessels. This loss in autoregulation results in hyperperfusion and disruption of the blood-brain barrier with resultant vasogenic oedema, as plasma constituents leave the vasculature and expand the extra-cellular space (23). This forms the underlying cause of eclampsia and hypertensive encephalopathy (23).

Generalised seizures occur in the presence of excessive release of excitatory neurotransmitters, massive depolarization of network neurons, and bursts of action potentials(16). In the pre-eclamptic patient this manifests as generalized tonic-clonic convulsions and in the absence of other neurologic conditions is known as eclampsia. Morbidity to both mother and fetus is increased and prolonged seizures can cause significant brain injury and later brain dysfunction(16).

Eclampsia can occur antepartum, intrapartum or postpartum and is most common in the third trimester with an increase in frequency as term approaches (24). Although uncommon in Europe with a reported prevalence of 2-3 cases per 10 000 births, it occurs more frequently in developing countries, with an estimated 16-69 cases per 10 000 births (3). Eclampsia is a
major cause of morbidity and mortality worldwide and accounts for more than 50 000 maternal deaths annually (25). The case fatality rate of eclampsia is 3-5% in low and middle income countries compared to 1% in developed countries (3,5). A three-year review from an academic hospital in Nigeria showed a prevalence of 13 per 1000 deliveries, with a case fatality rate of 8.5% (25). A retrospective analysis done in Durban showed an increase in the prevalence of eclampsia from 2.8 per 1000 deliveries to 6 per 1000 deliveries from 1980 to 1990. However, in the same period there was a slight decline in the case fatality rate from 12% to 9% (26). The high morbidity and mortality was attributed to low socioeconomic status, delayed referral to tertiary institution, non-availability of transport facilities and unbooked status of patients (25,26).

Another recently described phenomenon is the posterior reversible encephalopathy syndrome (PRES). Although its exact cause is unclear, it is thought to occur with disrupted autoregulation and endothelial dysfunction with or without subsequent vasogenic oedema (27). PRES is typically associated with severe hypertension but has also been described in patients with endothelial damage who experience rapid increases in blood pressure (28). Insidious onset of headaches, altered levels of consciousness, visual changes and seizures, associated with characteristic neuroimaging findings of posterior cerebral white matter describes this clinical syndrome. Reversibility is most frequent if PRES is promptly recognized and treated, however its effects may not always be reversible and its location may not necessarily be confined to the posterior regions of the brain (24,27).

Intracerebral haemorrhage, resulting from severe systolic or diastolic hypertension or sudden increases in blood pressure, has been reported to be the commonest cause of maternal mortality from hypertensive disorders of pregnancy, irrespective of the occurrence of
eclampsia (29). Diastolic blood pressures above 110 mmHg and persistent systolic values higher than 160 mmHg have been associated with significant risk of complications, which may result in PRES, eclampsia, stroke or all three (29).

Clinically evident neurological manifestations in patients without eclampsia or stroke include headaches, visual disturbances, and generalized hyperreflexia (24), which tend to resolve after the administration of magnesium sulphate. Blindness is rare and may be transient (9). The loss or disturbance of consciousness associated with eclampsia from the seizure itself, PRES or an intra-cerebral haemorrhage, may require intensive care unit admission with intubation and ventilation (26).

2.3.6 Pulmonary oedema

Pulmonary oedema is reported as the fourth commonest cause of maternal mortality in the United Kingdom. A review in 2012 showed estimated rates of acute pulmonary oedema in pregnancy of 0.08% to 0.5% (30). A five-year prospective study in the United Kingdom showed a prevalence of pulmonary oedema of 1.2 per 10 000 deliveries (25 out of 210 631 patients) (22). The aetiology is multi-factorial, often being a combination of left ventricular failure and non-cardiogenic pulmonary oedema. In some women, pulmonary oedema occurs as a result of increased hydrostatic pressure and a decreased colloid osmotic pressure resulting in fluid accumulation in the lung parenchyma, especially in the postpartum period (29, 30). Other women may demonstrate increased capillary permeability, and in some patients acute pulmonary oedema may be caused by iatrogenic fluid volume overload (24). Breathing and oxygenation is subsequently compromised, manifesting as severe respiratory distress that may require intubation. There are few studies demonstrating pulmonary oedema in pre-eclamptic women, let alone pre-eclamptic women at term (30).
2.3.7 Placental complications

Due to the compromised uteroplacental perfusion following the abnormal trophoblastic invasion, manifestations of pre-eclampsia can also be seen in the fetal-placental unit. This is a major contributor to the increase in perinatal morbidity and mortality rates. By 16 weeks of gestation, the vascular resistance in the uterine artery decreases markedly in normal placentation. However, in pre-eclampsia the abnormal placentation results in the vascular resistance remaining abnormally high, which subsequently is associated with oligohydramnios and fetal growth restriction (16,31).

Described as one of the most significant causes of maternal morbidity and perinatal mortality, placental abruption is defined as partial or complete separation of a normally implanted placenta before delivery occurs (14). Bleeding then follows from the decidua basalis, between the placenta and uterine wall. The combination of pre-eclampsia and placental abruption results in significant maternal morbidity, with hypovolaemia, coagulopathy and renal failure (32).

A Finnish overview in 2010 reported that the overall prevalence of placental abruption in all pregnancies varies from 0.4-1.0% (14). The occurrence tends to decrease with advancing gestation. One prospective case series in Tygerberg Hospital, Cape Town reported a prevalence as high as 20.2% in women with severe pre-eclampsia between 24 and 34 weeks’ gestation (11). Some studies have shown that women with chronic hypertension have a 2.4-fold increased risk for abruption compared to those without, which increases to 2.8-7.7-fold with superimposed pre-eclampsia or fetal growth restriction (32). A study in Norway showed an association of pre-eclampsia with placental abruption with an odds ratio for abruption ranging from 1.9 in mild pre-eclampsia to 4.1 in severe pre-eclampsia (33). The literature
suggests that of all risk factors, hypertensive disorders ranks the highest on the list for placental abruption.

2.4 Neonatal complications

Perinatal mortality is high in pre-eclamptic women and increases with eclampsia (3). Together, pre-eclampsia and eclampsia account for a quarter of stillbirths and neonatal deaths in developing countries. The perinatal mortality rate for pregnancies complicated by pre-eclampsia is three times higher in developing countries than in higher income regions (3).

A retrospective study at Tygerberg and Paarl Hospitals, Western Cape, from 2005-2006 studied 264 women with late-onset pre-eclampsia (≥34 weeks) and showed a mean gestational age at the time of diagnosis of 37 weeks, with a median birth weight of 2700 g. There were no early neonatal deaths. Of the five intra-uterine deaths, all due to placental abruption, only two occurred at ≥37 weeks. Sixty-nine babies (26%) required admission for special neonatal care, a much greater proportion than would be expected from pregnancies at ≥34 weeks’ gestation not affected by pre-eclampsia. However, the author did not state how many of these admissions were delivered to pre-eclamptic women at ≥37 weeks (34).

A study in the United Kingdom showed that 34.6% of 1087 pre-eclamptic women delivered after 37 weeks (22). Serious complications were reported in 151 (13.9%) of the pre-eclamptic patients. Of the 382 babies born after 37 weeks gestation, 14.7% required neonatal admission. Despite the fact that the focus of the study was on general outcome and not specific to gestational age, it does show that a significant number of babies born after 37 weeks gestation are admitted to neonatal units. This observation has also been stated by Sibai (35) and supports the need for more research to find out why this is the case.
The most important factor for survival of a healthy baby is gestational age (36). In a study from Tygerberg Hospital comparing expectant management to immediate delivery in severe early-onset pre-eclampsia, gestational age was the dominant consideration, with elective delivery often decided on after 34 weeks gestation (36). Although most pregnancies were remote from term, the study showed an increased survival rate at greater gestations, from 72% at 28 weeks to 92% at 29 weeks (36). This factor is further supported by data from the study mentioned above from Tygerberg and Paarl Hospitals on late-onset pre-eclampsia, in which there were no neonatal deaths (34).

A three-year prospective cohort study in Ireland from 1997-2000 on term patients confirmed that pre-eclampsia is associated with neonatal encephalopathy (37). One third of the encephalopathic babies, associated with hypoxaemia, were born to pre-eclamptic women at term. The mean umbilical cord arterial pH was lower in the babies born to pre-eclamptic mothers. The authors concluded that the fetuses of pre-eclamptic women may be hypoxaemic resulting from poor utero-placental perfusion (37).

While much of the above data are useful, it remains evident that overall the literature lacks studies specifically exploring the outcome of babies delivered to pre-eclamptic women at term.
2.5 Clinical management

The management of pre-eclampsia is subdivided according to severity of the disease. There is evidence that a patient with mild pre-eclampsia can be managed expectantly until fetal viability is reached. As long as she is treatment-compliant and there is no change in her clinical and laboratory parameters, the patient can be managed as an outpatient at a day unit, which would exist in most facilities in developed countries. However, in South Africa, admission to hospital is advised for all pre-eclamptic women using public service facilities (7). There must be close maternal and fetal evaluation as life-threatening severe pre-eclampsia can develop within a short space of time (6,21,38).

On admission to hospital, maternal evaluation consists of investigations to confirm or exclude worsening pre-eclampsia. This includes laboratory investigations to observe haematological, hepatic and renal function, as well as 12-24 hour urine collection for protein (6). Anti-hypertensive treatment should commence promptly. The Royal College of Obstetricians & Gynaecologists (RCOG) recommend emergency anti-hypertensive agents when BP ≥160/110 mmHg, and the American College of Obstetricians and Gynecologists (ACOG) recommends treatment for diastolic blood pressure levels of ≥105-110 mmHg (6,38). The University of the Witwatersrand (Wits) protocol adopted by academic hospitals in Johannesburg, including RMMCH, recommends emergency treatment at a BP ≥170/110 mmHg (7). In a case of acute severe hypertension, the aim of emergency treatment is to gradually bring down the blood pressure so that cerebral autoregulation is not compromised (21). Decreasing the blood pressure too quickly may cause uteroplacental hypoperfusion with fetal distress, or maternal cerebral ischaemia. Hydralazine, labetalol, or nifedipine are used for the acute management of hypertension, with methyldopa being the cornerstone for long term control (29,38,39).
It is vital that strict fluid balance is maintained. Due to the risks of fluid overload and pulmonary oedema, total fluid input should be limited to 85 mL/hour. It must also be taken into consideration that parenteral anti-hypertensive agents can cause a sudden drop in blood pressure; hence, preloading with 500 mL crystalloid fluid may be of value (38).

Although there are different schools of thought regarding the use of magnesium sulphate for prevention of seizures, the Wits protocol supports its use for patients with severe or imminent eclampsia, as does the RCOG. Certain factors must be taken into consideration when administering magnesium sulphate, such as awareness of toxic effects such as hypotension, depression of reflexes, respiratory depression and cardiac arrest, for which the antidote calcium gluconate must be readily available (7,29,38,39).

The decision to deliver the baby is multifactorial, wherein maternal and fetal wellbeing, past obstetric history and current gestation need to be considered. By the Wits protocol and supported by the National Institute for Health and Care Excellence (NICE) guidelines in the United Kingdom, patients with severe pre-eclampsia are delivered at 34 weeks gestation or an estimated fetal weight of 1.5 kg after administration of steroids for accelerating fetal lung maturity (6,7,39). The NICE guidelines advise that delivery can also be offered to pre-eclamptic women with mild to moderate hypertension at 34 to 36 completed weeks considering maternal and fetal conditions, risk factors and availability of neonatal facilities. Patients from 37 weeks and 0 days should be offered delivery within 24-48 hours (39). There is no justification in prolonging a term pregnancy with pre-eclampsia of any severity.

Irrespective of gestational age, delivery generally needs to be expedited in women with severe pre-eclampsia, poorly controlled BP requiring more than three agents, persistent
imminent eclampsia after administration of magnesium sulphate, HELLP syndrome, eclampsia, cerebral oedema, end-organ damage, intrauterine growth restriction, oligohydramnios, fetal distress, intra-uterine fetal death or placental abruption (6,38,39).

2.6 Mode of delivery

The operative delivery rate is increased in patients with hypertensive disorders and more so in patients with complicated pre-eclampsia (10). However, there are retrospective studies which have shown that induction of labour is not harmful to low birth weight infants. Vaginal delivery can be recommended for selected patients with severe pre-eclampsia who have no obstetric indication for caesarean section (10). However, a recent prospective study showed a four-fold increased risk of failed induction and a two-fold increased risk of caesarean section in pre-eclamptic women (31).

In the event of eclampsia, due to the unfavourability of the cervix and the need to deliver timeously, the caesarean section rate increases, documented to be 84.8% in a three-year review in Nigeria (25). There are no randomized clinical trials exploring the optimum mode of delivery in patients with severe pre-eclampsia (6). The decision to deliver by caesarean section should be individualized (6).

2.7 The pre-eclamptic patient at term

As stated earlier, there are few studies specifically focusing on pre-eclampsia and its management at term, although data are available on term subgroups in studies on pre-eclampsia at all gestations.
A retrospective cohort study carried out in 35 hospitals in Canada from 1991-1996 compared the birth weights of babies born to pre-eclamptic patients, to those born to normotensive patients from 32 weeks up to 42 weeks gestation (8). The authors looked at all babies delivered before 37 weeks gestation, and showed that those born to the pre-eclamptic mothers had lower birth weights compared to those born to normotensive mothers (p<0.01), after adjusting for confounding factors (smoking, maternal age, parity, obesity, prior small-for-gestational-age, prior large-for-gestational-age, anaemia and premature rupture of membranes). However, the babies born at ≥37 weeks’ gestation showed no statistically significant difference in mean birth weights when comparing both categories of patients. Contrary to common belief, the pre-eclamptic patients who carried to beyond 42 weeks gestation delivered babies that had a higher mean birth weight than those delivered to normotensive mothers, but the difference was not statistically significant. The focus of the study was the association of birth weights with gestation in pre-eclampsia, so there was no mention of any maternal or fetal morbidity. However, it can be deduced that babies born at term to pre-eclamptic women may have birth weights that are no different from those born at term to women who do not have pre-eclampsia. Interestingly, a significant proportion of pre-eclamptic patients (72%), carried uneventfully to term. Neither the gestation at the time of diagnosis nor the severity of the disease was mentioned. However, the study questions the hypotheses on the pathophysiology of pre-eclampsia. The findings contest the accepted ischaemic model, which states that there is decreased uteroplacental perfusion, as these patients, with pre-eclampsia at term, had a normal and perhaps even increased blood flow in the majority of cases.

This outcome suggests a heterogeneity in the pathogenesis of pre-eclampsia, that pre-eclampsia may manifest in two forms: 1) a restricted fetal growth early-onset pre-eclampsia, where affected patients deliver before term and are more likely to have decreased
uteroplacental perfusion; and 2) a normal fetal growth late-onset pre-eclampsia, with patients often presenting at and delivering at term, likely to have normal uteroplacental perfusion.

This theory is supported by a retrospective cohort analysis that was carried out in pre-eclamptic patients in Missouri, USA (40), where ischaemic placental disease was more frequent at pre-term than at term gestation (16% versus 5.5% respectively). Again, this suggests different pathophysiological pathways between term and preterm pre-eclampsia and hence a heterogeneity of the disease process. While this is a clinically evident heterogeneity, no studies support the presence of different microvascular or molecular pathogenetic processes between early-onset and late-onset pre-eclampsia.

A critical review in 2011 supports the above hypothesis that early- and late-onset pre-eclampsia are two distinct diseases, characterized by different biochemical markers, risk factors, clinical features and haemodynamic states. Early-onset pre-eclampsia is described to have a comparatively more severe disease profile than late-onset pre-eclampsia, with a stronger association with abnormal placentation, increased risk of multi-organ involvement, and adverse maternal and fetal outcome. However, due to the lack of studies and reviews no criteria have been established to define the two entities. More research is required to clarify the differences or similarities between the two groups(41).

The differing pathophysiology in the above two groups of patients has been further investigated and supported in a local prospective case-control study in Tygerberg Hospital done in 2007 (42). The study showed that the placentas of patients with early-onset pre-eclampsia weighed significantly less and had more ischaemic lesions when compared to those of pre-eclamptic women at term (42). Although the authors described the placentas of late-onset pre-eclamptic pregnancies as healthy, placental abruption in this group was still a frequent occurrence (eight out of 25 cases).
The HYPITAT Study was a European multicentre randomised controlled trial that investigated treatment of patients with gestational hypertension and mild pre-eclampsia at 36 to 41 weeks gestation, from 2005-2008 (43). Patients with severe pre-eclampsia were excluded. The aim was to compare induction of labour with expectant management in patients with mild pre-eclampsia and gestational hypertension beyond 37 weeks’ gestation. Although there were no maternal deaths, there was a high rate of morbidity. Of 756 women, 30% developed severe hypertension, and 15 patients (2%) developed HELLP Syndrome, 10% had postpartum haemorrhage and 2 patients (0.2%) had pulmonary oedema. The expectant management group included 11 of the 15 women who developed HELLP syndrome, as well as both patients that developed pulmonary oedema. No patient had placental abruption. Eighty-eight women in the induction group compared to 138 women in the expectant management group progressed to severe disease. The study showed that prolonging pre-eclampsia beyond 37 weeks added significant risk for maternal morbidity. The study did not look at the outcome of pre-eclampsia at term per se, and perhaps merging both pre-eclampsia and gestational hypertension was a weakness of this study. The HYPITAT study data certainly show that there is a high rate of maternal morbidity in pre-eclamptic patients at term. Morbidity rates for pre-eclampsia are likely even higher than found in the study, because of the merging of gestational hypertension with pre-eclampsia, and because severe disease and pre-eclampsia complications were part of the exclusion criteria for the study.

A 10-year cross-sectional retrospective study of 685 pre-eclamptic pregnancies from Saudi Arabia showed that 31% of stillbirths, and one out of seven neonatal deaths were in babies who were delivered at term to pre-eclamptic patients (9). Placental abruption, renal failure, coagulopathy and HELLP syndrome were the major maternal complications recorded. There
were two maternal deaths. Mild pre-eclamptic patients were managed expectantly and severe pre-eclamptics managed by immediate delivery. About 70% of the pre-eclamptic women delivered after 37 weeks. Whether these patients had mild pre-eclampsia and were managed expectantly up to term, or whether they were patients who presented at term with severe disease is unclear. Nevertheless, this is one of only a few studies where such a large number of pre-eclamptic mothers carried to term. Unfortunately the details of the outcome of the women at term were neither analysed nor reported on separately, and therefore cannot be commented on with respect to morbidity and mortality of the mothers and babies (9).
3.0 PROBLEM STATEMENT AND OBJECTIVES

Pre-eclampsia, as part of the hypertensive disorders of pregnancy, is the second most common cause of direct maternal mortality in South Africa. Being a disease that is exclusive to pregnancy, it is well known that delivery is the only cure.

Conflicting findings of fetal outcomes, and potentially poor maternal outcome even as one approaches term in pre-eclampsia, is what can be gathered from the relevant literature. Having reviewed the literature above, it becomes evident that there is a deficiency of data regarding the outcome of pre-eclamptic pregnancies at term. It appeared to be a feasible task to indulge in the wealth of information that patients offer at RMMCH, to fill in some evidence gaps regarding pre-eclampsia at term.

In a tertiary institution such as RMMCH, it was expected that patients with both mild and severe pre-eclampsia were treated in the facility. In addition, RMMCH delivers almost all women from its catchment area. These considerations made it feasible to study the prevalence of pre-eclampsia in this area, in the absence of significant referral bias.

3.1 Objectives of this study

1. To determine the prevalence of pre-eclampsia at term at RMMCH
2. To describe demographic and clinical factors in women with pre-eclampsia at term
3. To assess the severity of maternal disease in term pre-eclamptic patients
4. To assess the fetal outcome of pregnancies with pre-eclampsia at term
4.0 METHODS

4.1 Study design and study population

This was a prospective cross-sectional, descriptive study, carried out over a period of six months using a period sample. All women at term (≥37 weeks gestation by best estimate) who were admitted for pre-eclampsia were entered into the study and followed up until delivery. Patients who were admitted before term but delivered after 37 weeks were also entered into the study. Patients who did not attend antenatal clinic (unbooked women) were not included in the study because a true diagnosis of pre-eclampsia could not be made without a prior blood pressure assessment.

The definition of pre-eclampsia used in this study and endorsed by the ISSHP (International Society for the Study of Hypertension in Pregnancy) is described as the development of hypertension with proteinuria after 20 weeks gestation, which returns to normal postpartum. For women who booked after 20 weeks (a common occurrence in the population using RMMCH), a normal blood pressure and absence of proteinuria that preceded the onset of pre-eclampsia allowed classification of the patient as pre-eclamptic. Proteinuria was defined as ≥1+ on urine dipstick, or a spot protein/creatinine ratio ≥30 mg/mmol. Postpartum resolution of the hypertension and proteinuria could not be confirmed in this study.

4.2 Setting

This study was conducted in the obstetric unit at RMMCH, a district and regional hospital with tertiary functions, affiliated with the University of the Witwatersrand as a teaching hospital. The hospital delivers about 1000 women each month and only rarely refers difficult obstetric patients to other hospitals. It has only one referring midwife obstetric unit (Discoverers Clinic), which delivers about 60 women each month. The protocol guiding care
at RMMCH states that all women with pre-eclampsia, irrespective of gestational age, are admitted to hospital. Patients with mild pre-eclampsia are delivered if they reach term or if they present at term (7).

4.3 Sample size

It was hoped that 100 women could be included in the study, to allow a precision with a 95% confidence interval of at most 10% around observed proportion estimates.

4.4 Data collection

Every term pre-eclamptic patient admitted from 1 November 2012 to 30 April 2013 was entered into the study. After receiving informed consent from the participating patient, the researcher extracted the demographic and clinical data from the patient’s clinical file. The antenatal information was entered into the study data sheet immediately, and then the notes were followed prospectively up to delivery and postpartum. If a woman had already delivered by the time the researcher saw her for the first time, or a woman was admitted before term but delivered after 37 weeks, the information was entered retrospectively from the case notes. Explanatory variables that were collected included age, parity, gravidity, and a history of previous pre-eclampsia. The recorded details of the current pregnancy included the gestation at, and mode of delivery, as well as the birth weight and Apgar scores of the baby. The length of stay in hospital for the baby and the mother were also noted.

Consent from the 16 year old patient was taken after explaining the purpose of the study to her, reassuring her that she will not be re-numerated, nor will she or her baby be exposed to any harm, in layman’s terms in her language with the aid of a nursing staff member. An opportunity was also allowed for her to raise any questions or concerns, and to reiterate what
was explained to her to reflect her understanding of the consent and her participation in the study.

The outcome variables that were analysed were broadly divided into maternal and fetal. Maternal variables included severe hypertension (defined as a systolic BP $\geq 160$ mmHg or diastolic BP $\geq 110$ mmHg, on two occasions four hours apart or a single diastolic BP $\geq 120$ mmHg), eclampsia, pulmonary oedema (diagnosed clinically or radiographically), placental abruption (clinical diagnosis and macroscopic examination of placenta) and HELLP syndrome. Patients were classified as having HELLP syndrome by establishing the presence of thrombocytopenia (platelet count $<100 \times 10^9$/L) and raised ALT or AST levels (>40 IU/L). Fetal and neonatal outcomes were obtained from the delivery notes or the neonatal admission file if the baby was admitted. The fetal outcome variables included stillbirth, birth weight, Apgar scores, neonatal unit admission with reason, and neonatal death. The data collection sheet is attached as Appendix I.

4.5 Data analysis

Descriptive statistical methods were used, including statements of summary measures such as means, standard deviations, medians and ranges. Proportions were expressed as percentages. Analytic statistical methods were not employed.

4.6 Ethics

This study received approval from the University of the Witwatersrand Human Resources Research Ethics Committee, approval number M121060 (Appendix II). All participant information was kept confidential, and data sheets did not include any unique identifiers such as the patient’s name, birth date, hospital number or address. Hospital permission was obtained from the Chief Executive Officer of RMMCH.
4.7 Funding

Data capturing was conducted by the researcher and processed with the help of the supervisor. The researcher incurred all costs concerned.
5.0 RESULTS

5.1 The prevalence of pre-eclampsia at term at RMMCH

There were 6300 deliveries during the period 1 November 2012 to 30 April 2013. Seventy-eight women were diagnosed with pre-eclampsia and delivered at term, and were recruited for the study. Therefore, the prevalence of patients with pre-eclampsia who delivered at term at RMMCH was 1.2%.

5.2 Demographic and clinical factors in women with pre-eclampsia at term

Basic demographic and clinical information is shown in Table 2. The oldest patient in the study was aged 43 years, and the youngest was 16 years old. The mean age of the women was 27.3 years with a standard deviation (SD) of 5.8 years; 11.5% of women were older than 35 years. The median parity was one, with 35 primigravid women and six women having a parity of three or more. The parity range in this sample was zero to four. The median gestational age at delivery was 38 weeks. Gestational age was calculated by last normal menstrual period in 44 women (56.4%), with only 17 (21.8%) having had an early ultrasound scan (≤24 weeks). Twelve patients had a late ultrasound scan and five patients were dated by clinical palpation. Two patients in the study had pre-eclampsia previously. There were three pairs of twins.

A summary of clinical management of the pre-eclamptic patients is shown in Table 3. A variety of antihypertensive drugs was used, the most frequent being short-acting nifedipine (n=72; 93%). It was not always possible to distinguish from the notes whether this medication was given for acute BP lowering or for BP control maintenance, since it was used for both reasons during the study period. Both long-acting nifedipine and methyldopa were used for BP control maintenance. Intravenous labetalol was used for only three patients.

Thirty-eight patients received magnesium sulphate, of who 7 received only a 4 g loading dose, and 31 received maintenance dosages beyond the initial loading dose.
Fifteen patients went into spontaneous labour, while 28 had labour induced for maternal reasons, including two women who were ≥42 weeks’ gestation.

Fifty-one patients (65%) delivered by caesarean section, 52% for maternal reasons, and 48% for fetal indications. Although there was an overlap in some patients who required operative delivery from both maternal and fetal perspectives, the stronger indication was documented, either maternal or fetal. There were no elective caesarean sections in this study.

Certain indications for caesarean sections were a combination of maternal and fetal.

5.3 The severity of maternal disease in term pre-eclamptic patients

The complications of the pre-eclamptic patients are summarised in Table 4. Severe hypertension occurred in 59 (76%) of the women. Imminent eclampsia was recorded in 29 (37%) of patients and 9% of women had eclamptic convulsions. There was some overlap where patients had more than one complication. Six patients developed pulmonary oedema, three of whom required intensive care and ventilation, provided in the obstetric high care area.
as there were no beds available in the ICU. One of these patients developed pulmonary oedema in the antenatal ward and died shortly after delivering spontaneously, and is described in detail below.

Two patients had both eclampsia and pulmonary oedema, one of whom had to be intubated and ventilated. There were 13 patients with isolated thrombocytopenia and three had true HELLP syndrome by definition.

Three patients required blood transfusions for postpartum haemorrhage (PPH). One of these patients had a placental abruption, the second patient a retained placenta and the third patient had anaemia antenatally. They each received at least two units of red blood cells. No patient in this study had an intra-cerebral haemorrhage.

The median number of days admitted to hospital was five, with a range of 1-11. One patient stayed in hospital for 11 days as she was diagnosed with hyperthyroidism and was being investigated by internal medicine specialists.

*Patients may have more than one complication each*
Haematological and biochemical indices were documented at their highest level during the hospital admission and are shown in Table 4. For three patients, no blood results could be found. Twenty-two patients (29%) were anaemic (Hb ≤11.0 g/dL). The median haemoglobin level was 11.6 g/dL with a range of 6.2-16.3 g/dL.

Thirteen patients (17%) had low platelet counts (<150x10^9/L), with five patients having moderate thrombocytopenia. None had severe thrombocytopenia. The median creatinine level was 64.2 μmol/L, with a range of 27-153 μmol/L (a threshold of 100 mmol/L was used to define renal dysfunction as per the institution’s protocol). There was one patient who had renal failure based on oliguria, but she died before she required dialysis. One patient had a markedly elevated ALT reported as 10000 IU/L. Nine patients had abnormal AST levels ranging from 42-643 IU/L.

5.4 The fetal outcome of pregnancies with pre-eclampsia at term

Eighty-one babies were delivered, including three pairs of twins. One baby was lost to follow up and its details were not captured. The mean birth weight was 2695 g with a range of 1600 g to 5245 g. Fourteen were admitted for a median number of 2.5 days, with an interquartile range of 0-1. Two babies were admitted for meconium aspiration. Six were admitted for respiratory distress, all of whom were delivered by caesarean section. All but one of these six caesarean sections was done for fetal distress.

Three babies were admitted for birth asphyxia. The first baby was born to a 26 year old woman who had booked after 20 weeks’ gestation, with prior evidence of normal blood pressures and no previous pre-eclampsia. She had carried her pregnancy to 43 weeks by dates, and presented with severe hypertension, HELLP syndrome and placental abruption. The baby was delivered by emergency caesarean section for both maternal and fetal reasons. The baby weighed 3120 g and had an Apgar score of 6 at 5 minutes. The baby was diagnosed with birth asphyxia but did not develop Hypoxic Ischaemic Encephalopathy (HIE). He was admitted for observation and discharged on the next day. The second baby admitted for asphyxia was born to a 27 year old woman who booked after 20 weeks’ gestation and had normal blood pressures prior to admission. She was admitted at 39 weeks’ gestation with severe hypertension and imminent eclampsia and was maintained on magnesium sulphate. Following induction of labour, fetal distress developed, necessitating caesarean section. The baby weighed 3330 g and had an Apgar score of 7 at 5 minutes. He required intubation for apnoea. He was diagnosed with HIE I but discharged nine days later. The third baby was born by spontaneous labour to a 16 year old patient who booked before 20 weeks’ gestation and had no complications of pre-eclampsia. The baby weighed 3595 g, with an Apgar score of 8 at 5 minutes. The baby was admitted for three days for HIE I, and then discharged. There
were no stillbirths. There was one neonatal death from meconium aspiration born to the patient who died, as discussed below.

5.5 Maternal death

There was one maternal death in this study. She was a 28 year old para 2 at 38 weeks gestation by palpation. She booked after 20 weeks gestation, with no evidence of hypertension on her early visits. Her previous pregnancies were uneventful with no pre-eclampsia. She was admitted with severe hypertension, for BP control and delivery. During her stay in the antenatal ward she developed respiratory distress, which was initially mild but then worsened such that she was moved to the high care area for intensive management. She was treated for pulmonary oedema with intravenous furosemide, with minimal response. She was also oliguric and had serum urea and creatinine levels of 11.3 mmol/L and 128 μmol/L respectively. Simultaneously, she was found to be in labour, which progressed to the delivery of a live baby weighing 2440 g. There was meconium passage in utero and the baby aspirated. The baby had a recorded Apgar score of 8 at 5 minutes but died shortly after birth.
After delivery, the patient’s condition deteriorated to the point that she needed intubation and ventilation for refractory pulmonary oedema. With no ICU beds available, the resuscitation was performed in the high care area. Once she was stabilized with the support of inotropic drugs, a CT scan of the brain was arranged, which showed cerebral oedema but no intracranial haemorrhage. Almost 24 hours later, still on inotropes, the patient died. An autopsy was not done.
6.0 DISCUSSION

This study has found that significant morbidity accompanies pre-eclampsia at term, especially in terms of maternal complications. With seven cases of eclampsia and six cases of pulmonary oedema including one maternal death, the risks of pre-eclampsia at term should not be underestimated. Conversely, there appeared to be low morbidity and mortality in the newborn infants.

6.1 The prevalence of pre-eclampsia at term at RMMCH

This study showed a prevalence of pre-eclampsia at term of 1.2%. This estimate is likely to be close to a true prevalence because of the low likelihood of referral bias at RMMCH. The only missing numbers from the prevalence denominator are an approximate 360 births at Discoverers Clinic. Including these numbers in the denominator, assuming that no pre-eclamptic women delivered at that clinic (the protocol is to transfer such women to RMMCH), the adjusted prevalence remains 1.2% - a decrease from 1.24% to 1.17%.

The global impact of pre-eclampsia is 2-8% of pregnancies with a reported prevalence of 5-8% in the USA (3,6). The prevalence in this study may appear low relative to the statistics mentioned above, but it must be borne in mind that this is representative of a pre-eclamptic population at term, and excludes pre-eclamptic women before 37 weeks’ gestation. The statistics in the literature do not differentiate between term and pre-term pregnancies. Considering this fact, one is led to believe that a significant proportion of our pre-eclamptic patients make it to term or that many cases of pre-eclampsia only manifest clinically at term.
6.2 Clinical factors in women with pre-eclampsia at term

A variety of drug treatments was employed for treatment of hypertension. This may be attributed to rotation of junior and trainee staff from different medical institutions in Johannesburg, resulting in different approaches to the acute management of the hypertension in pre-eclamptic patients at term and deviations from the protocol at RMMCH. Unfortunately, the use of nifedipine for acute blood pressure lowering could frequently not be distinguished from maintenance treatment of hypertension. However, the frequent use of magnesium sulphate does indicate the clinical concern for the women that were included in this study. Despite 48.7% of women being loaded with and 40% of patients being maintained on magnesium sulphate, 9% complicated with eclampsia. In those patients who developed eclampsia, the data sheet did not stipulate whether the patient had received magnesium sulphate prior to the eclamptic episode. However, two out of seven eclamptic patients were not documented as imminent eclampsia. From that one can deduce that the magnesium sulphate was given as treatment of the eclampsia and not as prophylaxis. In general, clinicians at RMMCH do not use magnesium sulphate in pre-eclampsia unless the condition is considered severe or suggestive of imminent eclampsia. Perhaps this high incidence of eclampsia then should prompt a wider prophylactic approach.

6.3 The severity of maternal disease in term pre-eclamptic patients

Fifty-one patients (65%) delivered by caesarean section, about half for maternal reasons, and half for fetal indications. Although vaginal delivery is preferred for maternal considerations in pre-eclamptic woman, the caesarean section rate was high even for maternal indications and comparable to that experienced in Tygerberg Hospital, but similarly having a higher rate for maternal than for fetal indications (34). Studies have shown that there is an increased risk of failed induction and caesarean section in pre-eclamptic women (31). The study at
Tygerberg Hospital supported this finding by showing that 50% of their caesarean sections were performed for failed induction of labour or fetal distress after induction of labour (34). Short-term morbidity after caesarean section was not a significant problem, but long-term problems such as wound haematoma (possibly related to thrombocytopaenia) and subsequent wound sepsis could not be studied, because patients were not followed up through the puerperium.

Severe hypertension was diagnosed in about three quarters of the patients. Imminent eclampsia was recorded in 37%, all of whom received magnesium sulphate. Nine per cent of the patients complicated with eclampsia. This and the high proportion of women with severe hypertension, reflects the significant morbidity endured in pre-eclamptic patients at term. A 9% rate of eclampsia in a 1.2% proportion of cases of pre-eclampsia at term suggests an eclampsia rate at term of one in 1000 pregnancies, much higher than the two to three cases per 10 000 for eclampsia (at all gestational ages) quoted for developed countries (3). A comparable eclampsia rate for term pregnancies is not available in the literature. Related to eclampsia, intra-cerebral haemorrhage is an important cause of maternal mortality in South Africa (29). However, there were no cases of intra-cerebral haemorrhage in this study.

Compared to a reported prevalence of 0.08-0.5% (30), 7.7% of pre-eclamptic women at term in the current study complicated with pulmonary oedema, half of whom had to be intubated and ventilated and required intensive care, with one death. The author speculates that perhaps an obstetric critical care unit would have added much value to the management and outcome of these patients, particularly the patient who developed pulmonary oedema while admitted in the ward. The complication could have been detected earlier and promptly managed if she was in a critical care setting. Again, extrapolating from the 1.2% prevalence of pre-eclampsia
at term, the prevalence of pulmonary oedema at term here would be about 1:1000 pregnancies, much higher than the 1.2 per 10,000 deliveries reported in the United Kingdom (22). The finding is even more concerning when one remembers that the United Kingdom rate is for pregnancies of all gestational ages and for all causes of pulmonary oedema, not only pre-eclampsia.

In this study one patient had a placental abruption, in keeping with the national prevalence of 0.5-2% (18). However, the sample size was too small to make any conclusion about the frequency of abruption in association with term pre-eclampsia, other than to state it was not a common finding. From the available data on these patients, there seemed to be little evidence of placental disease, suggesting that term pre-eclamptic patients perhaps have predominantly maternal disease with relatively few placental and fetal adverse events, in keeping with recent observations regarding late-onset versus early-onset pre-eclampsia (34, 41, 42, 44). However, growth restriction diagnosis was rarely attempted in these patients and formal screening for small-for-gestational-age was not performed on the babies after delivery. The observed 18% rate of low birth weight babies could suggest placental insufficiency or misclassified gestational age.

Thirteen patients had thrombocytopenia, some of whom were managed as HELLP syndrome based on their clinical status. This number is not included in the group of patients documented with true HELLP syndrome. The prevalence of true HELLP syndrome by definition was 3.8% in this study, lower than the reported prevalence of 20% in severe pre-eclamptic patients as quoted by Curtin and Weinstein (18), but similar to the 5.2% found at Tygerberg Hospital (11). Contrary to the haemoconcentration found in patients with pre-eclampsia, 29.3% of women had a haemoglobin level ≤11.0 g/dL on admission. Neither the
type nor the cause of the anaemia was a focus of the study and therefore was not documented. All patients who are booked at the antenatal clinics receive iron and folate. Therefore, the question of anaemia and its association with HIV and anti-retroviral drugs, or other factors, comes into question. However, the HIV status of the women was not recorded in the data.

6.4 The fetal outcome of pregnancies with pre-eclampsia at term

The major fetal complications encountered were meconium aspiration, from which one baby died, respiratory distress and birth asphyxia. All babies admitted for respiratory distress were delivered by caesarean section, of which all but one was for fetal distress. This leads one to question whether the respiratory distress was due purely to the placental insufficiency with metabolic acidosis related to pre-eclampsia, misclassification of gestational age, or was related to caesarean section itself, which is known to be associated with mild respiratory distress (45, 46) also associated with borderline maturity at 37-38 weeks (37). The neonatal admission rate in this study was high (17.5%), similar to the 14.7% found in the United Kingdom (22). It must yet again be remembered that the studies cited encompass all pre-eclamptic women, whereas this study included only women at ≥37 completed weeks. As noted by Sibai, and evidenced by this study, the majority of neonatal admissions from hypertensive mothers are those who are delivered at term. The reasoning is unknown and emphasizes the need for research in this area (35). The high caesarean section rate comes into question as a possible reason, given the concern about respiratory distress mentioned above.

6.5 Limitations of the study

The small study population affected the precision of the reported estimates, and rendered it difficult to comment on some of the findings. However, the severe outcomes in this study such as eclampsia and pulmonary oedema are significant enough to warrant a larger
population-based study. The significance of the findings could perhaps have been enhanced if
the researcher compared them to a control group of term non-pre-eclamptic women and to a
group of pre-eclamptic women remote from term. The researcher relied on patients’ files for
recording of clinical observations and bedside investigations. This allowed room for error in
measurements beyond the control of the researcher, and possible misclassification of
hypertensive disorders and gestational age. Unbooked patients were excluded from this study
and therefore those patients who presented for the first time to hospital with unclassified
proteinuric hypertension or eclamptic episode were not documented. However, in the
researcher’s experience unbooked women presenting at term are a rarity at RMMCH. It was
also not possible to document resolution of hypertension after delivery, to exclude chronic
hypertensive disease misclassified as pre-eclampsia. During the study time period the
laboratory staff were upgrading their data systems, therefore results were not always readily
available. Patients were managed on whatever results were available and on their clinical
condition. Hence, patients with thrombocytopenia were often managed as HELLP syndrome,
in the absence of certainty about haemolysis. Haematocrit levels are not routinely recorded in
the patients file, and this posed a limitation to the more accurate assessment of the anaemia
and haemoconcentration observed. To the best of the researcher’s knowledge, none of the
patients entered into the study were referrals, and RMMCH did not refer any hypertensive
patients to other hospitals, and therefore this sample is likely to be representative of a pre-
eclamptic population at term. Also, in this study, the focus was on outcomes and it is unlikely
that any serious complications were missed. The likely impact of a gap in the denominator
resulting from the exclusion of Discoverers Clinic deliveries has been discussed earlier.
6.6 Conclusion

It seems clear that there is a tendency to poor maternal outcome as one approaches term in pre-eclampsia. This study demonstrated that maternal complications such as eclampsia and pulmonary oedema are common in pre-eclampsia at term. Clinical vigilance and expertise are as important for pre-eclamptic women at term as they are for those who are pre-term. The importance of maternal stabilization before embarking on delivery or surgery must always be considered.

As demonstrated by this study, and suggested by the little data available in the literature, the fetal morbidity and mortality seems to be lower in the neonate of a term pre-eclamptic woman. This sheds more light on the theory of the heterogeneous pathophysiology of pre-eclampsia, which may manifest as: 1) a restricted fetal growth syndrome (early-onset pre-eclampsia), where affected patients deliver before term and decreased uteroplacental perfusion may be evident; and 2) a normal fetal growth syndrome (late-onset pre-eclampsia) where patients progress to term and have normal uteroplacental perfusion, as supported by Dahlia in a critical review of both early- and late-onset pre-eclampsia(41).

There is a need for a larger epidemiological study where term pre-eclamptic patients can be compared to pre-term pre-eclamptic patients. It may also be of value to follow these two groups of patients through the puerperium to assess for complete resolution of the complications or residual disease subsequent to the severe complications such as pulmonary oedema and eclampsia.
